<p>Since 1948, the Coastal Engineering Research Center (CERC) and its predecessor, the Beach Erosion Board (BEB) have gathered wave data from U.S. coastal locations. Staff and pressure-sensitive gages, generally shore-based, were used to obtain the data; a few gages were operated at offshore locations. Wave records were initially 7-minute pen and ink records taken six times a day, but more recently, 1,024-second digital records on magnetic tape taken four times daily have been used to determine significant wave heights and</p> <p>(Continued)</p>		

periods. Summaries of significant heights and periods for 19 gage locations provide useful information on ranges, and annual and seasonal variations of wave climate.

PREFACE

This report is published to provide coastal engineers and coastal researchers with summaries of nearshore wave measurements from 19 locations along the Atlantic, gulf, and Pacific coasts. The work was carried out under the wave measurement program of the U.S. Army Coastal Engineering Research Center (CERC).

This report was prepared by Edward F. Thompson, Hydraulic Engineer, under the supervision of Dr. D. Lee Harris, Chief, Oceanography Branch.

The success of the CERC wave measurement program has been a result of the efforts of many people involved with the program since 1948. The assistance provided by Dr. Harris in the planning and preparation of this report is greatly appreciated. Particular recognition is given to the following people who designed, built, installed, and maintained the wave gages and associated electronics: C.M. Hare, F.W. Kellum, N.F. Lang, E.A. Maiolatesi, W.E. Robertson, C.H. Shepherd, Jr., and L.C. Williams.

Comments on this publication are invited.

Approved for publication in accordance with Public Law 166, 79th Congress, approved 31 July 1945, as supplemented by Public Law 172, 88th Congress, approved 7 November 1963.

To obtain Kelvin (K) readings, use formula: $K = (5/9)(F - 32) + 273.15$.

WAVE CLIMATE AT SELECTED LOCATIONS ALONG U.S. COASTS

by
Edward F. Thompson

I. INTRODUCTION

In support of its mission to conduct research on coastal phenomena of engineering importance, the Coastal Engineering Research Center (CERC) and its predecessor, the Beach Erosion Board (BEB) have operated wave gages in the nearshore environment for more than 25 years. The results of this effort provide the coastal researcher and the coastal engineer with important data on waves arriving at U.S. coasts in response to a variety of meteorological conditions; however, an equally important result is the specification of the annual and seasonal significant wave height and period climate at various coastal locations.

Knowledge of the ocean wave climate is important for planning coastal operations, estimating coastal sediment movement, designing coastal structures, and for other applications. However, because recording and analyzing reliable wave climate data are expensive and time consuming, there is a paucity of field wave data. Thus, the primary purpose of this report is to present summaries of significant heights and periods from the BEB-CERC field wave-gaging program at the 19 locations shown in Figure 1. A secondary purpose is to provide details and a perspective on the various wave measurement, recording, and analysis systems used by BEB-CERC. Similar wave-gaging programs are ongoing in shallow water along the southern California coast (Seymour, et al., 1976) and in deep water along Canadian coasts (Wilson and Baird, 1972).

Although there is presently no suitable substitute for accurate nearshore wave measurements, data obtained from the gages must be carefully interpreted. The waves being measured must be considered: Are the waves breaking or have they already broken? For surface gages, are these deep-water waves not yet affected by refraction and shoaling? These questions are discussed in Section II.

Aside from the variability of the waves being measured, the ability of the wave recording and analysis system to translate the waves in nature into accurate and useful results must be evaluated. Several important problems in the BEB-CERC system were probably unavoidable in a wave recording and analysis system under development for two decades. Different gage types, recording schemes, and methods for analyzing wave records have been used. Also, many gaps exist in the recording sequences. Each of these factors can introduce biases in the summarized data.

Three basic wave gages have been used in the BEB-CERC wave data collection program: Two staff gages (the step-resistance gage and the continuous-wire gage) and an underwater pressure-sensitive gage. The gages and the wave recording schemes used are discussed in Section III.

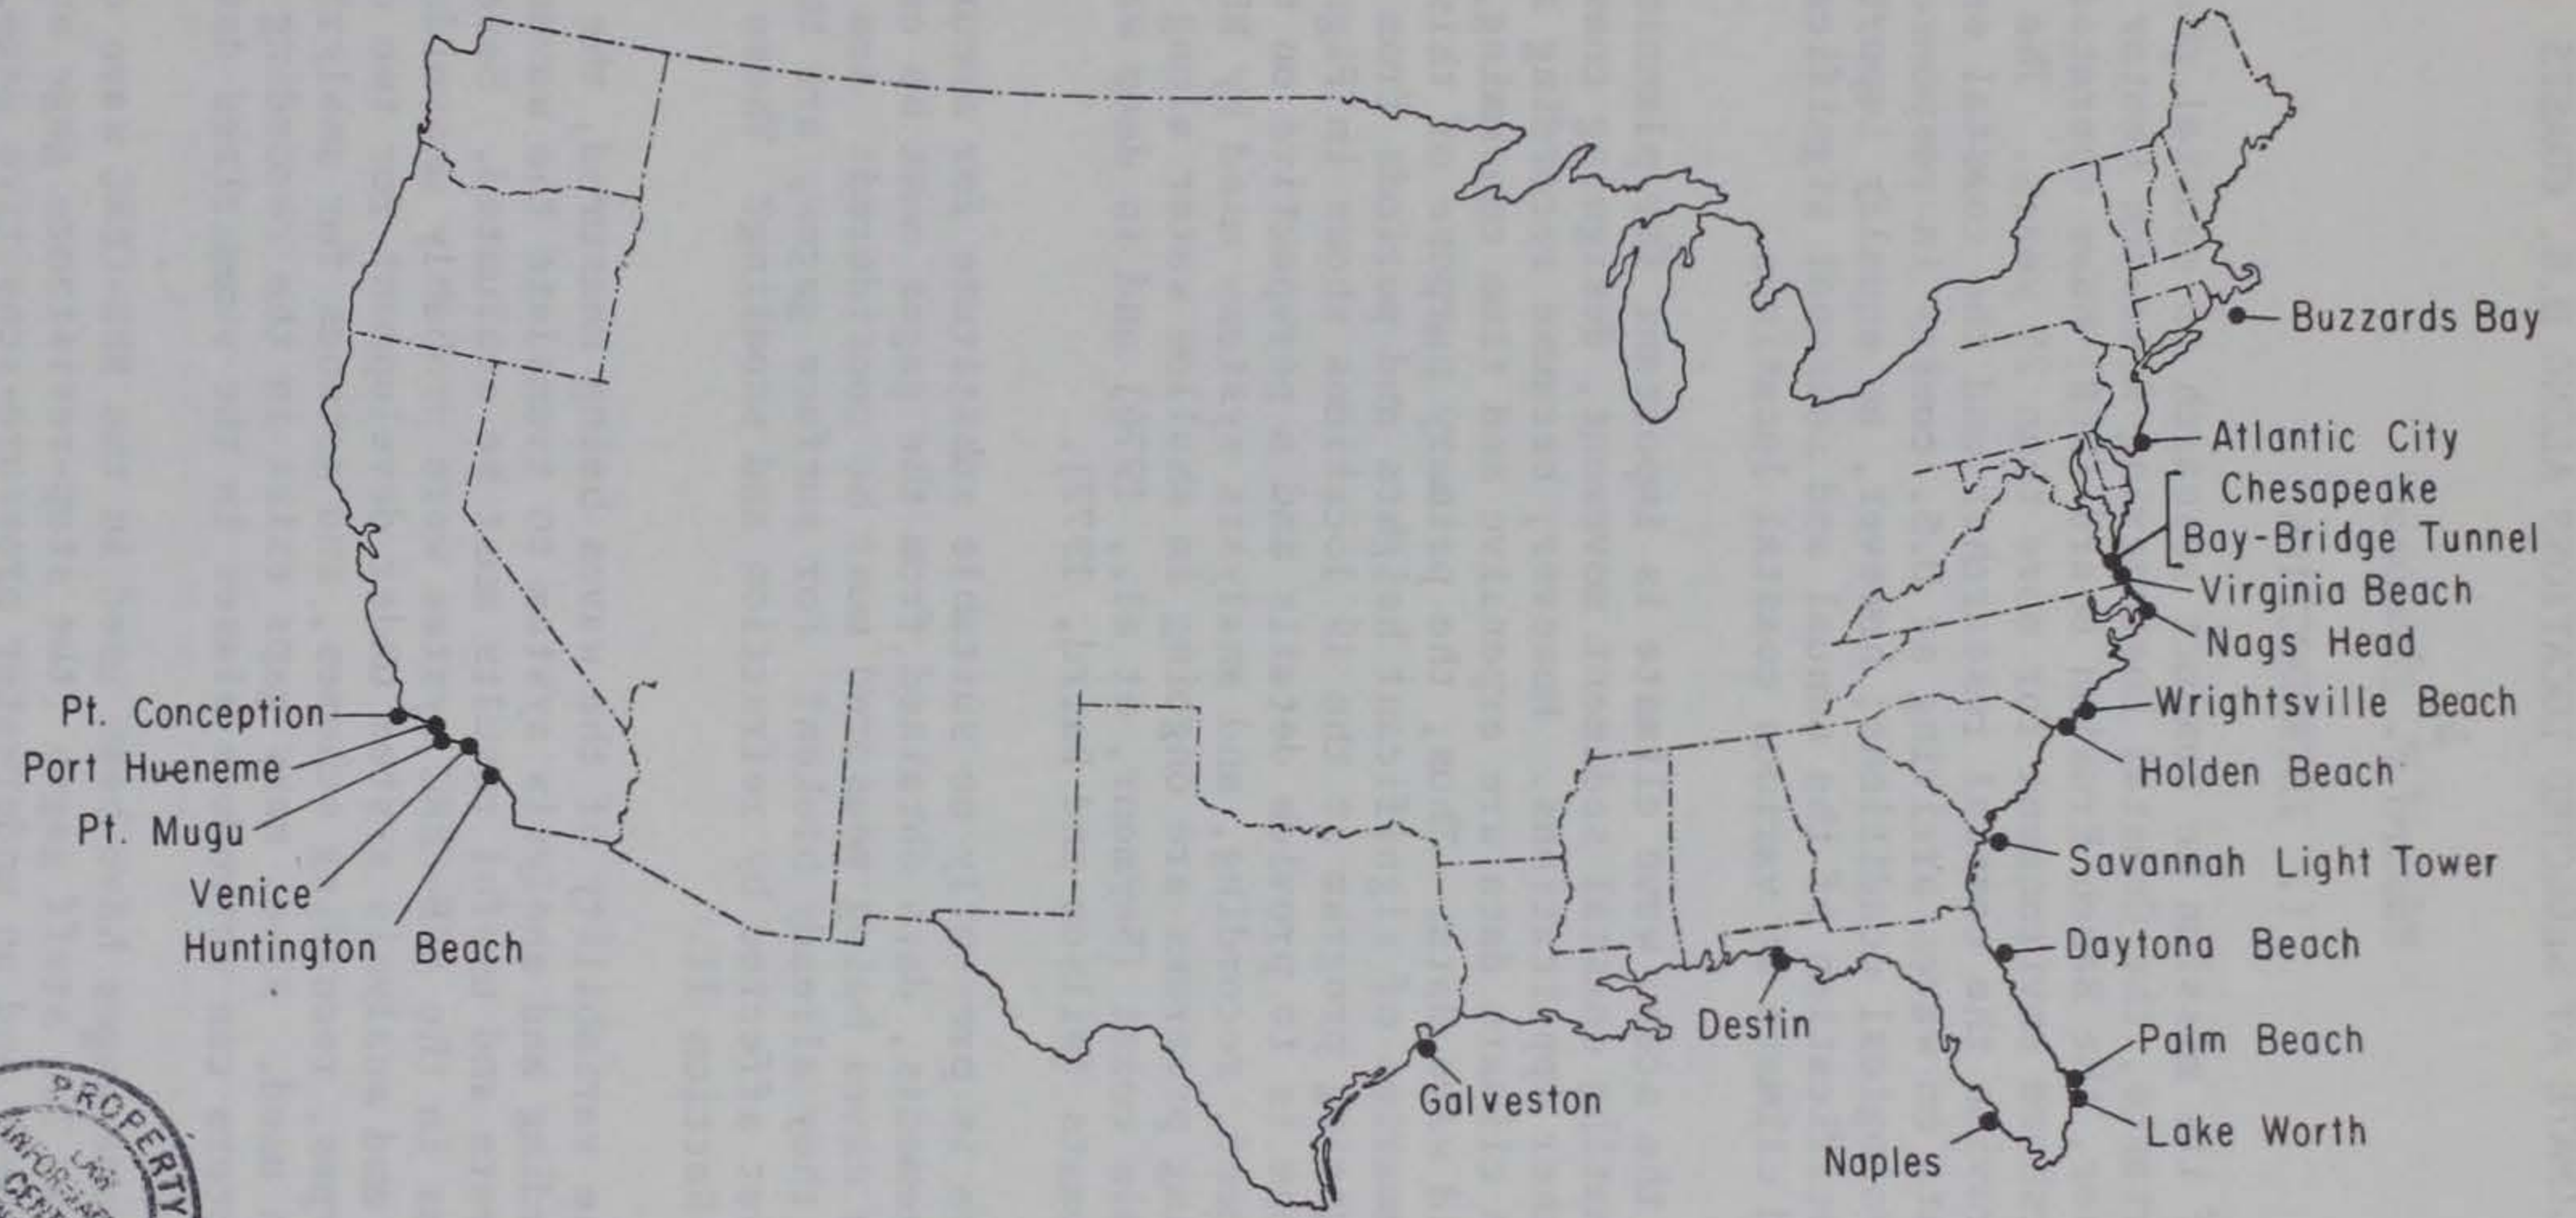

Figure 1. BEB-CERC wave gage locations.

Data recording and analysis techniques are discussed in Sections IV, V, and VI. Section IV discusses the different methods used by CERC for analyzing pen and ink records; Section V discusses the recording and spectral analysis of CERC's digital wave records on magnetic tape. In Section VI, significant wave heights and periods obtained from pen and ink records are compared with results from digital records.

The dependence of annual wave summaries on data analysis techniques and coastal location is described in Section VII.

The contents and format of the summaries of significant wave height and period are explained in Appendix A. Most summarized data were obtained with staff gages ranging from 4.6 to 13.7 meters (15 to 45 feet) in length and mounted on or near the seaward end of a pier. The ocean bottom at the gages ranged from 4 to 30 meters (13 to 100 feet) below mean sea level (MSL); however, none of the shore-based gages were in water deeper than 7.6 meters (25 feet).

The summaries, including results from both digital and pen and ink data, are presented in Appendix A for locations on the Atlantic coast, the gulf coast, and the Pacific coast.

II. NEARSHORE WAVE CHARACTERISTICS AT THE GAGES

Waves traveling from deep water into shallow water are modified by such processes as refraction, shoaling, and reflection. When several wave trains with different frequencies are present, these modifications can be complex. In such cases, energy transfer between wave trains can also be important.

Several different wave trains, each with a different wavelength and coming from a different, clearly defined direction, are usually visible in clear aerial photos of coastal waves. The photos often show short, choppy sea waves superimposed on several trains of long, regular swell waves. An example of multiple wave trains is shown in Figure 2.

Energy spectra obtained from CERC gages support the hypothesis that several wave trains with different energy and frequency are common (Thompson, 1974; McClenan and Harris, 1975). Examples from the Atlantic, gulf, and Pacific coasts are shown in Figures 3, 4, and 5. These data also indicate that occasionally, finely tuned unimodal spectra do occur.

Aerial photos of good quality are useful for observing wave modification and often show a remarkable change in the relative dominance of different frequency wave trains as the waves move into very shallow water nearshore. Some low-frequency wave trains which are nearly invisible offshore amidst higher frequency waves, have been observed to increase in prominence very nearshore to the point that, in the breaker zone, the train totally dominates the shorter waves present (Harris, 1972a; McClenan and Harris, 1975; U.S. Army, Corps of Engineers, Coastal Engineering Research Center, 1975, p. 3-4). This phenomenon is shown in Figure 6.

Figure 6. Aerial photo showing superimposed trains of sea and swell waves south of Port Hueneme, California, on 3 August 1960. The train of swell waves is nearly invisible offshore but is dominating the breaker zone.

Since offshore bottom topography, coastal exposure, and local currents are different at every coastal location, the coastal wave climate can also differ. Wave height can vary considerably, particularly alongshore between points on a given nearshore depth contour (Harris, 1972a; McClenan and Harris, 1975; U.S. Army, Corps of Engineers, Coastal Engineering Research Center, 1975, pp. 2-65 to 2-77; p. 2-112). This variability is expected to be small for short distances along a coastal area with relatively uniform topography and exposure.

Wave frequency can usually be considered unchanged as waves move into shallow water; aerial photos generally indicate no loss of integrity of waves during the refraction and shoaling processes. However, in some situations, a wave in shallow water can break down into several shorter waves (Galvin, 1972; McClenan and Harris, 1975).

Wave frequency, as determined from a measurement point fixed in space, can also be modified by local currents. A current opposing the waves decreases the frequency; a following current increases the frequency.

The placement of wave gages by BEB-CERC has been limited by practical considerations. Since staff gages require a rigid mounting structure, most BEB-CERC staff gages have been located near the seaward end of ocean piers to gain optimum exposure to waves from different directions and to keep the gages seaward of the breakers for most wave conditions. However, most waves reaching the gages have been appreciably altered by bottom effects. At times, waves arriving at a gage have already negotiated an offshore bar seaward of the pier on which the gage is mounted; occasionally, high waves break seaward of the gage.

Ocean waves measured at the gages are rarely either deepwater waves or breakers; however, accurately measured and properly interpreted, the waves provide a good indication of the wave frequencies and wave heights approaching shore.

III. WAVE GAGES AND RECORDERS

1. Wave-Gage Types.

a. Step-Resistance Gage. Most step-resistance gages used in the wave-gaging program at BEB and initially at CERC, were designed and fabricated at BEB (Williams, 1969). These gages used electrical contact points along the staff to sense water surface elevations. The contact points are embedded, usually at 0.06-meter (0.2-foot) intervals, in 1.5-meter-long (5-foot) epoxy resin sections which are designed to slide easily into a steel or aluminum H-beam frame securely clamped to a piling, steel pipe, or other rigid support.

Step-resistance gages are classified as spark plug, parallel, or relay types, and are all similar in appearance. The spark plug type was used only in the beginning of the BEB wave-gaging program. The parallel type has been developed for use in saltwater of fairly constant salinity.

The relay type is designed for use in either saltwater, freshwater, or water of highly variable salinity.

b. Continuous-Wire Gage. The continuous-wire gage now used by CERC is a type manufactured by the Baylor Company, Sugar Land, Texas, and consists of two parallel stainless-steel cables in tension, spaced about 23 centimeters (9 inches) apart. Braces at both ends of the cables are firmly attached to a rigid support. Spacers are usually placed at intermediate points along the cables to ensure proper separation. The gage produces an electrical output proportional to the length of cable above the short circuit imposed by the sea surface.

This rugged gage is capable of operating very well along any exposed ocean coast and is insensitive to biological fouling or to small variations in salinity; however, it is unsatisfactory for use in freshwater, or brackish water. Failure of the gage is frequently caused by lightning damage to gage circuitry. Continuous-wire gages are presently used at all CERC staff-gage locations where electrical conductance of the water is sufficiently high.

c. Pressure-Sensitive Gage. Submerged pressure-sensitive gages are useful at locations with cold winters where ice would form on a staff gage and render it inoperable and at locations where no suitable structure for gage mounting is available or where a staff gage would interfere with navigation. Pressure gages can be placed on the ocean floor in shallow water.

The first pressure gage used by the BEB had a bellows that changed in length in response to water pressure variations (Williams, 1969). The bellows movement was coupled to the core of a linear differential transformer which produced an electrical signal that was amplified and recorded. A new pressure-gage design was adopted in 1964 which used strain gages rather than a bellows (Peacock, 1974).

A pressure-gage record is always damped in comparison to a staff-gage record, because the pressure pulse due to a surface wave is attenuated with increasing depth of measurement. For intermediate and low-frequency waves, the pressure record can usually be compensated for gage submergence with frequency-dependent compensation factors (Esteva and Harris, 1970); for high-frequency waves with wavelengths shorter than twice the water depth, the pressure record is often attenuated beyond recovery.

Local currents can affect apparent wave frequencies. A wave in a current with a component of velocity in the direction of wave travel passes a fixed gage more rapidly than a wave of equivalent length outside the current. Thus, the apparent frequency of the wave in the gage record is inappropriately high for the wavelength. The frequency-dependent compensation factor applied to such a record and the resultant wave height estimate would be too high. Similarly, for a wave in a current with a component of velocity opposing the wave motion, the wave height estimate would be expected to be too low.

Pressure gages are susceptible to biological fouling; however, with routine maintenance, fouling has not been a major problem with gages now used by CERC.

2. Comparison of Gage Types.

Since the three types of wave gages do not respond identically to a given sea state, each may be associated with a small individual bias. To evaluate the relative responses, a continuous-wire gage, a step-resistance gage, and two pressure gages (2.6 and 4.3 meters below MSL), were mounted 3.7 meters (12 feet) apart on the end of Steel Pier in Atlantic City, New Jersey (Esteve and Harris, 1970). Wave data were recorded as 20-minute digital records on magnetic tape, and 12 records per day for 1 week were analyzed. The standard deviation of each digital record, referred to as the root-mean-square (RMS) elevation, was computed as an estimate of wave height. RMS elevations for pressure gages were compensated according to linear wave theory to conform to surface measurements. RMS elevations from the pressure- and step-resistance gages were plotted as a function of RMS elevation from the continuous-wire gage (Fig. 7). Data from both pressure gages compared favorably with data from the wire gage. However, most data from the step gage were higher than data from the wire gage. Significant height estimates (four times the RMS elevation) obtained from a step-gage record appeared to be about 1 foot higher for low and moderate wave conditions and about 20 percent higher for high-wave conditions (Fig. 7).

One reason why the step-resistance gage is biased toward higher wave readings is that waves striking the gage tend to run up the inside of the H-beam which supports the gage (Fig. 8; see also Fig. 12 in Williams, 1969). During long-term unattended field use, thick biological growth on the gage can slow gage response to wave troughs, and severe growth can continue to short out the gage at a particular elevation even when the sea surface drops momentarily below that elevation.

3. Wave Recorders.

a. Recorder Types. Data from two types of wave recorders have been used for this study. The earlier BEB main recorder type was the pen and ink strip-chart recorder; sample records are shown in Figures 9 and 10. The pen motion is controlled by a voltage signal which increases and decreases in response to momentary changes in sea surface elevation at the gage. The pen and ink recorder was activated by timer-driven switches at regular intervals.

A digital magnetic tape recording scheme has been implemented at CERC within the last 10 years. In this recording scheme, the voltage signal from the gage is converted to a frequency-modulated signal, transmitted to the CERC laboratory via telephone line, reconverted to a voltage signal, converted to a digital signal, and finally recorded in a binary-coded decimal format on 0.5-inch magnetic tape at the rate of four data points per second. The recorder operates continuously, switching automatically to a new gage or group of gages every 20 minutes.

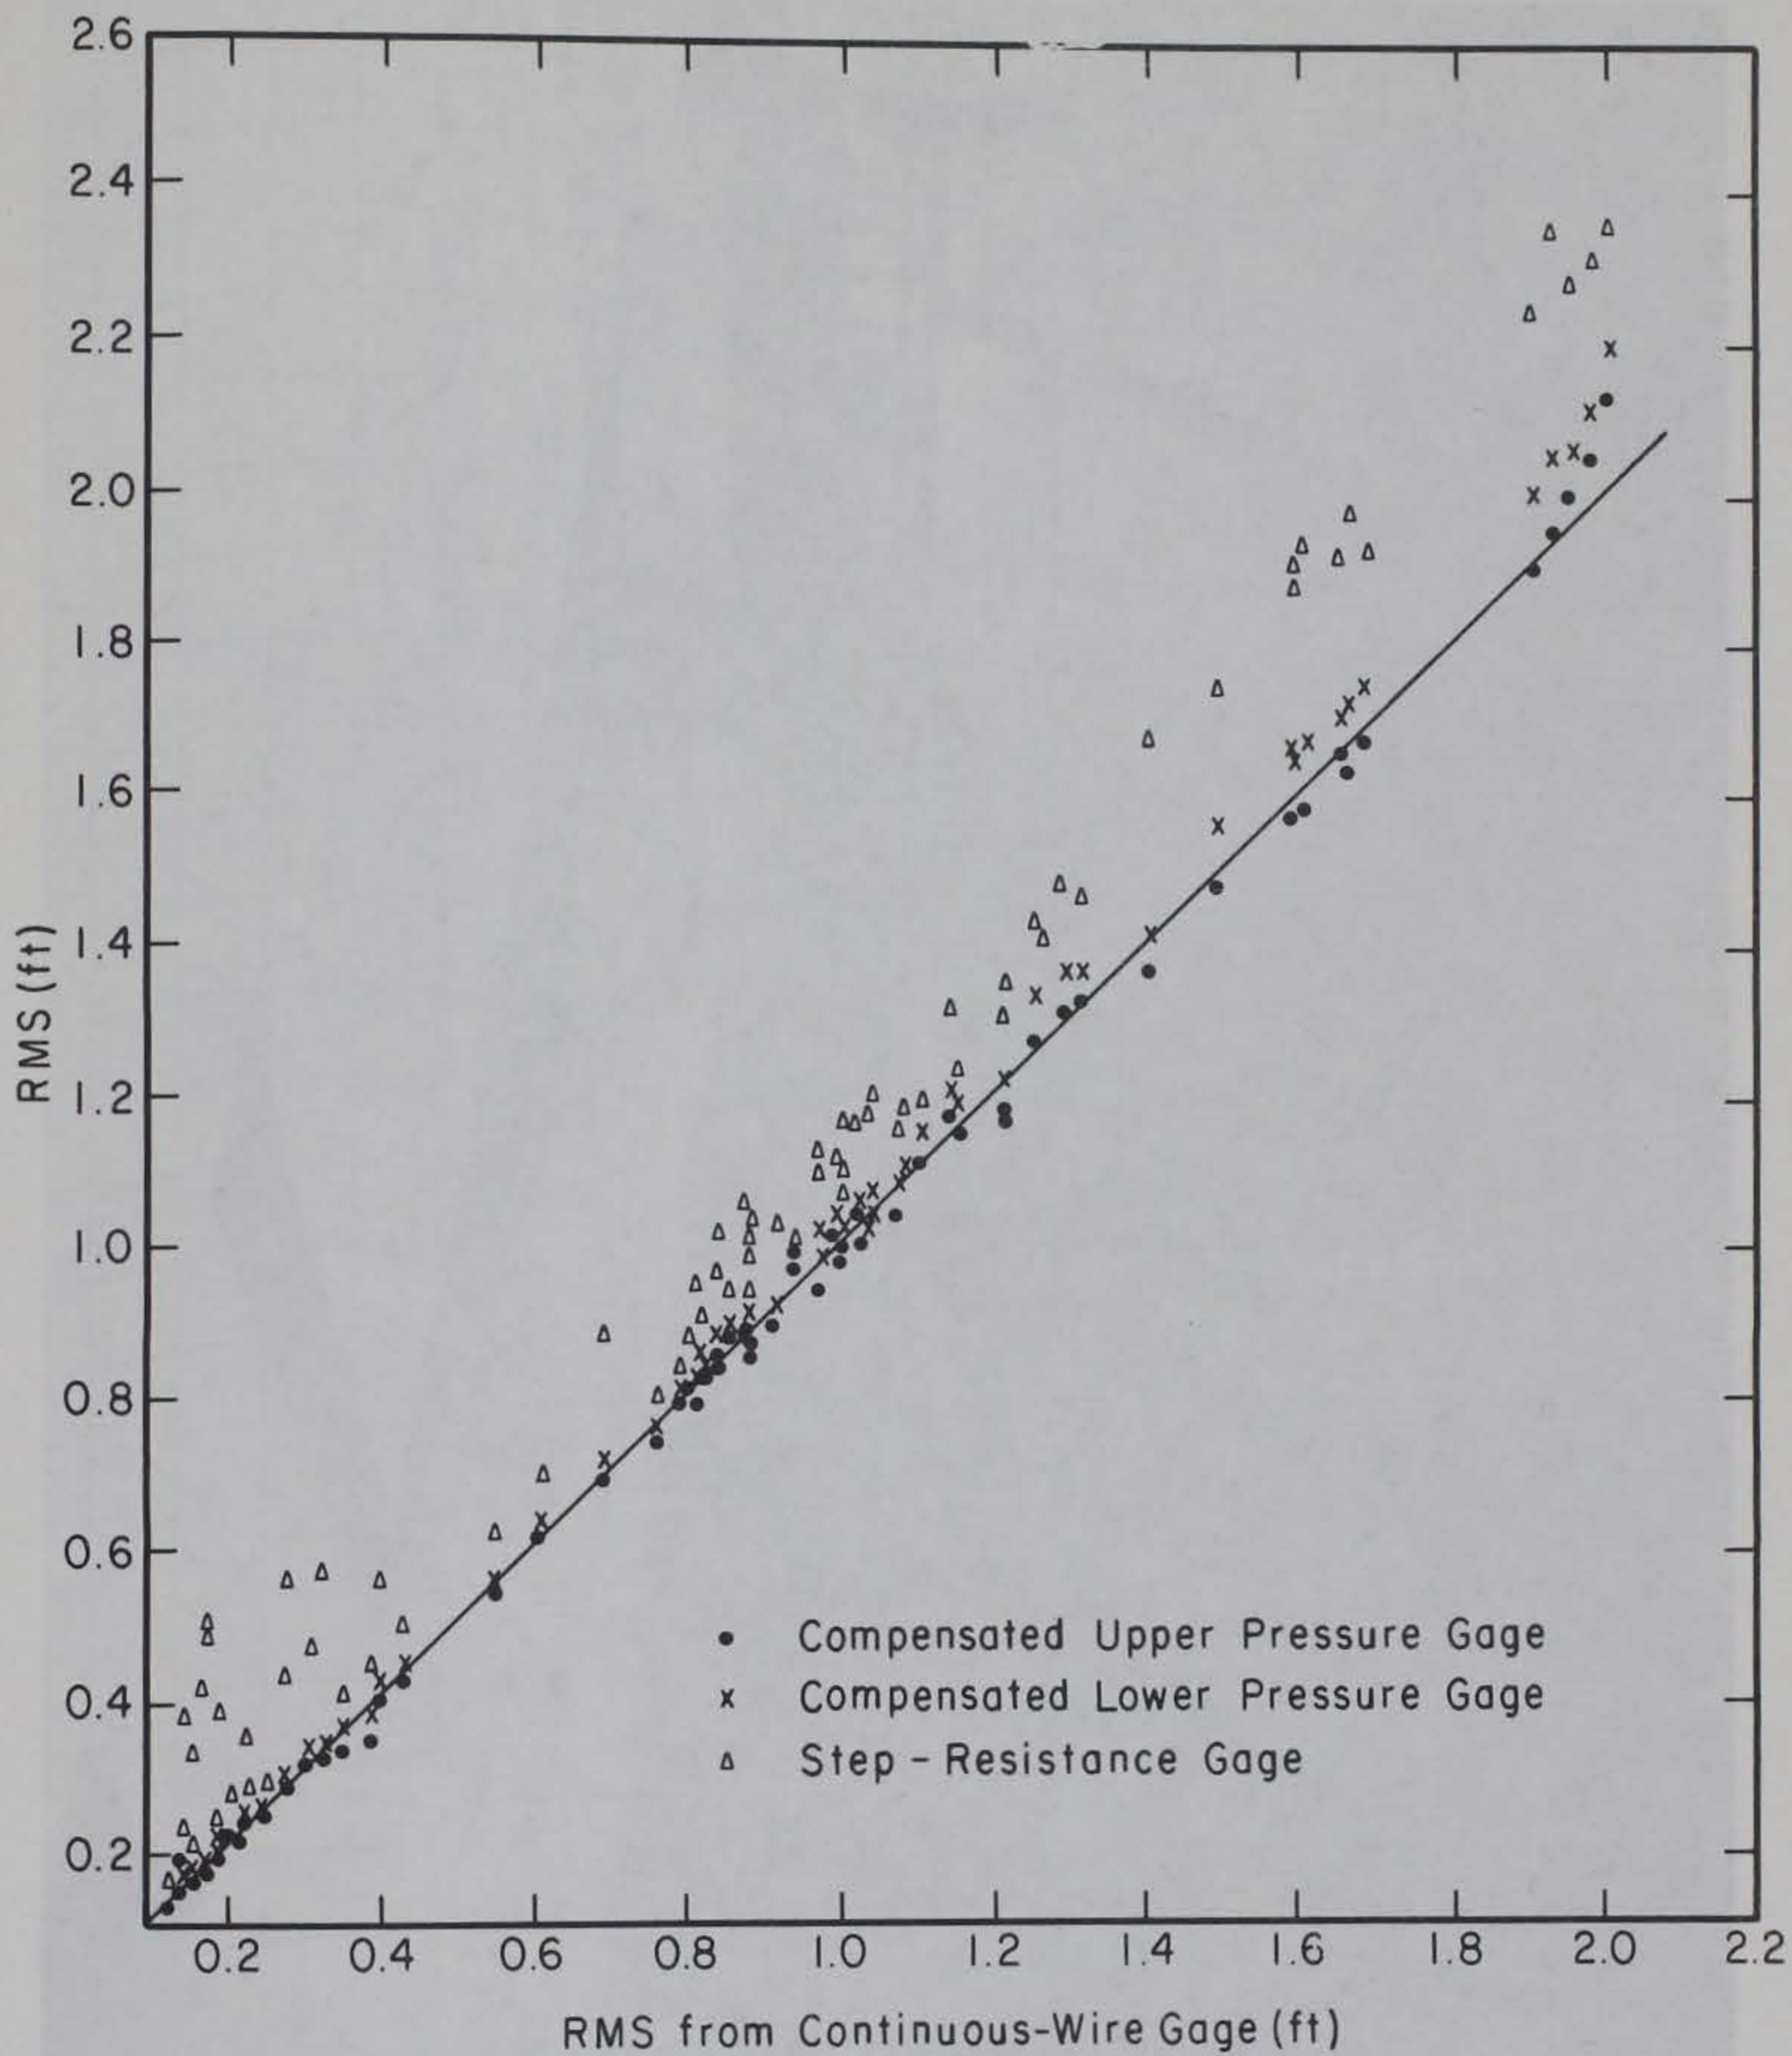

Figure 7. Comparison of root-mean-square (RMS) sea surface elevations from pressure- and step-resistance gage records with those from continuous-wire gage records (Esteva and Harris, 1970).

a

b

Figure 9. Examples of wave records from: (a) Lake Worth, Florida, at 2215 hours, 27 January 1966; (b) Nags Head, North Carolina, at 1300 hours, 15 April 1975.

Data Type	Significant Height (ft)	Wave Period (s)
Pen and Ink	8.0	8.0
Digital	5.9	8.0

Figure 10. Example of wave record from Wrightsville Beach, North Carolina, at 0100 hours, 27 May 1972.

b. Changes in Recording Procedure. For most of the recorded data, the pen and ink strip-chart recorder ran for 7 minutes each time it was activated (at 4-hour intervals before August 1971 and 6-hour intervals after that date). After April 1975, the standard record length was decreased to 4 minutes. Records taken before January 1970 were on curvilinear paper; records from 1970 to the present are on rectilinear paper (Fig. 9).

Before 1966, all recorders were located at the gage sites and were tended by local people under contract to mail the completed rolls of chart paper to BEB-CERC, to install fresh rolls of chart paper when necessary, and to report any malfunction of the equipment. After 1966, the signals from some gages were sent instantaneously over telephone lines to the CERC laboratory. Since November 1968, the signals from most gages have been routinely sent over telephone lines, converted to digital form, and recorded on magnetic tape.

Digital signals from four gages were recorded simultaneously after March 1971. This procedure is accomplished with an electronic multiplexer which successively samples each of the four gage signals every 1/16 second, so that a data point from any particular gage signal is obtained every 1/4 second.

One 20-minute digital record per hour was obtained for each gage signal before February 1973, accommodating 12 gage signals by the recording sequence. However, since that date more than 12 gage signals have been received and the recording sequence modified to provide one 20-minute record every 2 hours for each gage signal.

Although digital records for each gage recorded are available every 1 or 2 hours, only four digital records per day are routinely analyzed. Pen and ink records taken during time periods covered by digital records are not routinely analyzed, but are used mainly for quality control and for special tests. The pen and ink records also provide a backup when the digital recorder is inoperative. If known in advance that pen and ink records will be analyzed, records longer than 4 minutes can be obtained.

4. Gage and Recorder Problems.

Maintaining an operating wave gage in coastal waters is difficult. To minimize problems, BEB-CERC generally performed routine maintenance twice a year on both step-resistance and pressure gages which consisted of a thorough cleaning and recalibration of the gage and often cleaning and repainting of the H-beam or other supporting structures. Routine maintenance of continuous-wire gages has not been necessary.

In spite of regular maintenance and improvements in wave-gaging systems, interruptions in the recording sequence have been caused by storm waves, lightning, fire, electricity cutoffs, biological organisms, vandals, and errant boats striking the gage.

Some of the common problems which result in missing records with the onsite pen and ink recorders are: (a) Sticking of the recorder pen in one position or running out of ink, (b) failure to promptly replace the chart paper rolls, (c) failure to date the records, and (d) mailed records never reaching CERC.

A major problem with the digital magnetic tape recorder is electronic noise in the data. Noise is fairly common on telephone lines, and although analysis procedures can cope with some types of noise, it is still a problem. Minor, less frequent problems are tape-reading difficulties, power failures, and recorder malfunctions.

IV. ANALYSIS OF PEN AND INK WAVE RECORDS

1. Introduction.

Despite the many problems associated with efforts to measure ocean waves, CERC has accumulated a large volume of pen and ink records. Unless the sea is very calm, these records usually indicate waves with a variety of heights and periods and often show a complex interaction between several distinct wave trains with different heights and periods. Examples of recorded waves are shown in Figure 9.

For practical use, the information in the pen and ink records is usually reduced to a few concise parameters which define a sea state and can be used to form statistical summaries of sea states. These simplified data can be used more readily than the original pen and ink records for the solution of most coastal problems.

Each wave record is usually characterized by a wave height parameter and a wave period parameter. The most commonly used characteristic wave height has been the "significant" height. Significant height was originally proposed by Sverdrup and Munk (1948), who recommended that the wave height estimate be based on the higher waves in the record. They proposed the average height of the one-third highest waves in the record as a reasonable estimate of wave height. The concept of a significant wave height has proved useful in coastal and ocean engineering, and numerous methods have been developed for estimating significant height.

A single measure of wave period has not been as clearly defined. Most pen and ink record analysis methods give no more than a rough averaging of periods of the higher waves; this estimate is usually referred to as the "significant" period.

BEB-CERC has used several different methods to estimate significant wave height and period from pen and ink records; these methods are discussed below.

2. Analysis Methods for Pen and Ink Wave Records.

a. First BEB Method. This first method of pen and ink wave record analysis (started by BEB in 1948) used an average wave period (significant period), measured crest-to-crest, determined from sequences of high,

well-defined waves in the record. The record length was usually 7 minutes, and was divided by the significant period to obtain an estimate of the total number of waves in the record. The heights, measured from crest to preceding trough, of the highest one-third waves were then measured and averaged to give a significant wave height for the record.

b. Second BEB Method. The second BEB method for pen and ink record analysis, adopted in 1953 or 1954, was quicker than the first method. This procedure required the person performing the analysis to select a 1-minute sample from the record which contained the highest and most uniform waves. Then, a wave-period template was used to estimate a significant period for the high, uniform waves. According to the significant period, the height of the first, second, or third highest wave in the 1-minute sample was measured and used as an estimate of the significant wave height.

c. CERC Method. In January 1965, a third pen and ink record analysis was adopted at CERC. This method used the full 7-minute wave record, was fairly fast, and was more discriminating than the second BEB method. A wave-period template was used to estimate the period of the higher and more uniform waves in the record. The length of the record divided by the significant period, gave an estimate of the total number of waves in the record. Assuming that the Rayleigh distribution applied for heights of individual waves in a record (see U.S. Army, Corps of Engineers, Coastal Engineering Research Center, 1975, pp. 3-5 to 3-11), the rank, n , of the wave which would theoretically have a height equal to the significant height, was determined. The height of the n th highest wave in the record was measured and used as the estimate of significant height. Step-by-step instructions for this analysis method are given in Appendix B.

This third analysis method is now used at CERC when significant wave heights and periods must be estimated from pen and ink records. However, the procedure is no longer carried out routinely.

3. Comparison of Pen and Ink Record Analysis Methods.

Methods used by BEB-CERC for analyzing pen and ink wave records often give different results when applied to the same wave records. These methods, particularly the second BEB method which required selection of a 1-minute sample, are also fairly subjective; the results are dependent upon the individual analyzing the record. The CERC method is more objective, and is considered to give more reliable results.

Since results of all three pen and ink record analysis methods are included in this study, some of the old BEB pen and ink records were reanalyzed using the CERC method. Linear regression equations were computed, relating results from the CERC method to the old analyses; significant height estimates derived were found to average about 20 percent lower than height estimates from the BEB method. Significant period estimates were reasonably comparable to each other. Additional details of this study are in Appendix A.

Harris (1970) compared the CERC method with other accepted methods for estimating significant wave height and period from pen and ink records and found correlations above 0.9 with wave height estimates from a method based on the highest crest and the lowest trough, as recommended by Tucker (1961). Harris also found high correlations between height estimates from the CERC method and the average height of the one-third highest waves in the record.

Methods of estimating wave period from pen and ink records considered by Harris (1970) were the CERC method, the average period between upward zero crossings, the average period between all waves, and the average period of the one-third highest waves. Correlations between estimates from the CERC method and the other methods were below 0.25 except for estimates from the zero-crossing method which gave correlations of 0.39 to 0.55.

V. ANALYSIS OF DIGITAL WAVE RECORDS

Techniques for recording and analyzing digital wave data in the last 15 years have improved considerably, and digital data are now attractive for several reasons. Digital data permit direct computer analysis, providing objective, repeatable estimates of significant height and period, and facilitate computation of wave variance or energy spectra which provide more information about the wave field. Spectra are also useful for solving some engineering problems.

CERC has been recording digital wave data since 1966; data from each gage are recorded at the rate of four points per second for a duration of 20 minutes every 1 or 2 hours. The standard CERC computer analysis uses 4,096 data points or 17 minutes and 4 seconds of data for each gage record processed; one record is processed every 6 hours for each gage. The standard analysis has been applied to most of the available acceptable digital data.

The first step in the CERC computer analysis program is to edit the digital record selected for analysis. Editing routines check for non-numeric characters or anomalous spikes and jumps in the record, and usually interpolate across a few bad or highly questionable data points; however, if the data contain more than five consecutive bad points or if more than 2.5 percent of the data points are bad, the routines reject the record as unsuitable for analysis.

If the record is accepted, the distribution function for the accepted data points and its first five moments are computed. The second and third moments are checked for a reasonable comparison against criteria supplied in the program.

After the credibility of a record has been verified, the program applies a data window to the data points of the form:

$$\frac{y(t)}{2} \left(1 - \cos \frac{2\pi t}{T} \right),$$

where $y(t)$ is the data point at time, t , and T is the record length. Application of a data window results in greater resolution for the frequency spectrum of the record. This procedure decreases the variance of the data points, and the variance or energy of the original data points, $y(t)$, is retained for estimating significant wave height. The use of data windows is discussed by Bingham, Godfrey, and Tukey (1967), Briscoe (1972), and Harris (1974).

After application of the data window, the program computes the variance spectrum, often called the energy spectrum because the potential energy in the wave record is proportional to the variance of the record. This computation involves assigning a part of the energy to each of 1,024 different frequencies. The spectrum is computed by a method based on the finite Fourier transform technique (Bingham, Godfrey, and Tukey, 1967; Tukey, 1967). To gain statistical stability and to reduce extraneous detail, the energy assigned to several successive frequencies in the computed spectrum is combined to give an array of energy estimates for a series of frequency bands of equal width (usually 0.0107 hertz).

In the standard CERC procedure, spectra are then normalized by dividing the energy assigned to each band by the total spectral energy over a specified range of frequencies. The range of frequencies which the total energy represents is referred to as the *normalization interval*. The normalization interval for surface wave records is usually 0.033 to 1.0 hertz for staff gages, which corresponds to wave periods of 1 to 30 seconds. Normalized spectra facilitate investigation of spectral shapes; examples computed at CERC are shown in Figures 3, 4, and 5.

The spectral analysis of data from submerged pressure-sensitive gages requires some additional calculations. The pressure gage senses a signal which is attenuated by the water over the gage. The amount of attenuation increases with the frequency of the surface waves and the depth of submersion. To compensate the spectrum of a pressure-gage record for attenuation, the variance assigned to each spectral band is multiplied by a factor (greater than or equal to one) derived from linear wave theory. The compensated spectrum is then renormalized.

Compensated pressure spectra are generally based on a more restrictive normalization interval, with a lower high-frequency cutoff than spectra derived from staff gage records. The selection of a high-frequency cutoff for compensated pressure spectra becomes increasingly difficult and critical as water depth over the gage increases.

The standard CERC spectral analysis program is occasionally modified for special applications; e.g., successive data points obtained in laboratory experiments may be separated by a smaller time interval than the standard 0.25-second interval used for field data. A longer time interval between data points and a longer duration of the record are required for harbor resonance studies.

The standard analysis program has also been applied to data not acquired in the standard format. In these cases, the program controls are usually chosen to make the analyses as comparable as possible to the standard analyses. Nonstandard analyses have not been included in this study.

Complete spectra are difficult to interpret for many engineering applications; significant wave height and period provide a convenient and readily used indicator of wave conditions, and for compiling statistical summaries of sea states, are easier to handle than complete, but complex descriptions of wave conditions.

Significant wave height for a digital wave record is approximately equal to four times the standard deviation of the record (U.S. Army, Corps of Engineers, Coastal Engineering Research Center, 1975, p. 3-12). For pressure records, this estimate of significant height must be suitably compensated to represent surface wave conditions. The magnitude of the compensated significant height is quite sensitive to the high-frequency cutoff applied to the spectra, especially for data from relatively deep gages or from locations with considerable high-frequency wave energy.

At CERC and other organizations, the dominant wave period for a digital record is defined as the period associated with the frequency at the middle of the spectral band with maximum energy. Since the spectral bands are of equal frequency width, the analysis provides uniform resolution in frequency. However, wave period is the reciprocal of frequency, and the resolution in period is not uniform. If the data are summarized for equal resolution in period, the energy assigned to a greater number of individual frequencies must be combined for short periods than for long periods.

Only a discrete set of period values are possible with the standard digital analysis. When the data are summarized in equal width period intervals, a given period interval may be distorted by one more or less period value than is representative for the interval. This effect is important only for adjacent intervals encompassing few discrete period values or frequency bands; e.g., Table 1 shows that the 13- to 14-second interval contains no period values, and that the 8- to 9-second interval contains two period values while both the 7- to 8- and the 9- to 10-second intervals contain only one. Thus, a false concentration of period values could be expected in the 8- to 9-second interval.

When two wave trains occur, the present system of defining the significant wave period emphasizes the longer period waves. In using uniform period increments, the shorter period would be favored. The present system was adopted because of: (a) Directness, (b) an accurate knowledge of wave frequency is more important than an accurate knowledge of wave period in many practical problems, and (c) longer waves are more important than shorter waves of similar height in many applications. Complete information about all wave trains can be obtained only from the full spectrum.

Table 1. Wave period resolution of the CERC procedure for analyzing digital wave records.

Wave period interval (s)	Number of frequency bands in interval
1 to 2	47
2 to 3	15
3 to 4	8
4 to 5	4
5 to 6	4
6 to 7	2
7 to 8	1
8 to 9	2
9 to 10	1
10 to 11	1
11 to 12	0
12 to 13	1
13 to 14	0
14 to 15	1
15 to 16	0
16 to 17	1
17 to 18	0
18 to 19	0
19 to 20	0
20 to 21	1

Another consideration in interpreting wave period for the band with maximum energy in the spectrum arises from peculiarities of the wind-wave generation process (Barnett, 1972; Hasselmann, et al., 1973). Nonlinear transfer of wave energy between different frequencies during wave generation causes a net gain of energy in the low-frequency part of the spectrum. The energy transfer process also focuses most of the energy into an increasingly narrow band of frequencies.

Waves traveling away from a generation area tend to segregate according to frequency as low-frequency waves move faster than high-frequency waves. The low-frequency waves also attenuate more slowly than the high-frequency waves.

Thus, wave conditions can arise where a train of low-frequency waves provides the maximum energy in any single spectral band; a train of higher frequency waves contains more total energy but the energy is spread over several frequency bands. In such conditions, the standard analysis would report the period of the low-frequency waves.

VI. COMPARISON OF RESULTS FROM SIMULTANEOUS DIGITAL AND PEN AND INK RECORDS

1. Introduction.

BEB-CERC accumulated a large volume of significant wave heights and periods obtained from pen and ink records. CERC is now in the process

of accumulating and analyzing a considerable number of digital wave records. Both of these data files represent a large investment of money and effort, and provide valuable documentation of waves at many U.S. coastal locations.

In using significant heights and periods from both pen and ink and digital records in this study, the derivation is sometimes ignored; however, this approach can be misleading. Pen and ink record analyses can depend on the method used to obtain them. With data recorded and analyzed by two totally different procedures, discrepancies in the analyses are even more likely.

Engineers are more familiar with pen and ink records because these records have been available longer than digital records. Does the engineer need to make special allowances when using heights and periods derived from digital records? This question is best answered by the following specific questions:

(1) How do individual significant height and period estimates from pen and ink records compare with those from digital records taken at about the same time?

(2) How do statistics such as mean and standard deviation of the distribution functions compare?

(3) How do the distribution functions compare?

These questions are discussed in this section; conclusions are briefly summarized at the end of the section.

2. Description of Data Sample.

To investigate the compatibility of significant wave heights and periods from digital and pen and ink records, an 8-month sample of both types of data, taken between September 1971 and April 1972, has been analyzed. The digital data (discussed in Section V) were 1,024-second records taken four times daily from gages at six Atlantic coast and two gulf coast locations; 7-minute pen and ink records were also taken four times daily from the same locations, each record beginning within 30 minutes of a digital record. Pen and ink records were then analyzed by the CERC method (Section IV, 2).

3. Comparison of Results.

a. Individual Estimates.

(1) Significant Height. Significant height estimates from digital and pen and ink records taken at an Atlantic coast gage location (Savannah Light Tower, Georgia) are compared in Table 2. The table is a joint distribution of the ratio of pen and ink height estimate to digital height estimate as a function of digital height estimate.

Table 2. Comparison of significant wave height estimates from digital and pen and ink records, Savannah Light Tower, Georgia, September 1971 to April 1972¹.

$\frac{H(\text{PI})^2}{H(\text{Digital})^3}$	H(Digital) in feet								Total ⁴	Cumulative total ⁵	Row average ⁶

Cumulative total ¹⁰		499	455	256	126	43	15	2			
Average ¹¹		0.873	0.977	0.996	1.014	1.000	0.958	0.950	0.980		
Percent in 1.0 ± 0.1 ¹²		20	45	62	63	68	62	50	52 ¹³		

¹Estimates taken within 30 minutes of each other; total of 499 observations.

²H(PI) = Significant height in feet from pen and ink records by the CERC method (see App. B).

³H(Digital) = Four times the standard deviation of the digital record.

⁴Total number of cases in specified height ratio intervals.

⁵Cumulative total of the total number of cases in specified height ratio intervals.

⁶Average digital height estimate for all cases in specified height ratio intervals; indicates if certain height ratios tend to associate with high or low wave conditions.

⁷Number of times the height estimate ratio and the digital height estimate falls within the specified intervals.

⁸Total number of cases in specified digital estimate intervals.

⁹Average digital height estimate for all 499 observations.

¹⁰Cumulative total of the total number of cases in specified digital estimate intervals.

¹¹Average height ratio for all cases in specified digital height intervals; indicates if certain wave height levels tend to associate with high or low wave height ratios.

¹²Percentage of cases in each digital height interval in which height estimates were within 10 percent of each other.

¹³Percentage of all 499 observations with height ratios between 0.9 and 1.1.

Over half of the pen and ink estimates in Table 2 are within ± 10 percent of the corresponding digital estimates; however, a few height ratios are substantially different from unity. Seven of the pen and ink estimates differ from the digital estimates by more than ± 40 percent. The table shows a decrease in percentage variability of pen and ink estimates for higher wave conditions, indicating that the dispersion between estimates may be absolute rather than wave height dependent.

Table 2 shows no consistent tendency for pen and ink height estimates to fall above or below digital estimates; the average pen and ink height estimate was 98 percent of the average digital height estimate. This difference in averages amounts to only 0.05 foot.

Comparisons of height estimates from seven other gage locations lead to the following similar conclusions: (a) About half of the digital and pen and ink estimates agree within ± 10 percent, (b) 4 out of 100 estimates can differ by ± 40 percent or more, and (c) percentage variability of estimates decreases with increasing wave height.

Correlations between estimates in the full 8-month data sample (Table 3) also indicate that, in general, individual significant height estimates compare favorably (between 0.93 and 0.96 for every location). Correlations between digital and pen and ink height estimates obtained by Harris (1970), using the same methods for two 1-month data samples from Atlantic City, New Jersey, also fall within this range.

For high wave conditions at some locations, the pen and ink height estimates tend to be relatively high; e.g., Wrightsville Beach, North Carolina (Table 4). This tendency derives from the nonlinear wave shapes characteristic of high, long waves in shallow water (see Fig. 10). In the analysis of the pen and ink record in Figure 10, individual wave heights were measured as the difference between crest and preceding trough elevations. The wave height estimate from the corresponding digital record is based on the total potential energy in the record. For a record with sharp crests and flat troughs, the energy in each wave is considerably less than that in a sinusoidal wave of the same height (Fig. 11). The pen and ink height estimate is over 2 feet higher than the digital estimate for the record shown in Figure 10.

Pen and ink height estimates are based on 7-minute records; digital estimates are based on records nearly 2.5 times as long. Since high waves sometimes occur in groups (Rye, 1974), height estimates from the shorter 7-minute records can be unrepresentatively high or low due to poor statistical sampling.

Although height estimates derived from pen and ink records of high, long waves in shallow water tend to be excessive, the reverse would be true for purely sinusoidal waves of uniform height. Ideally, this pen and ink height estimate would be the height of the waves. The digital estimate would be four times the standard deviation or 1.414 times the individual wave height. Thus, the pen and ink estimate would be 30

Table 3. Correlation between significant wave estimates from digital and pen and ink records taken during September 1971 to April 1972.¹

Location	Height estimates		Period estimates

¹⁰Cumulative total of the total number of cases in specified digital estimate intervals.

¹¹Average height ratio for all cases in specified digital height intervals; indicates if certain wave height levels tend to associate with high or low wave height ratios.

¹²Percentage of cases in each digital height interval in which height estimates were within 10 percent of each other.

¹³Percentage of all 760 observations with height ratios between 0.9 and 1.1.

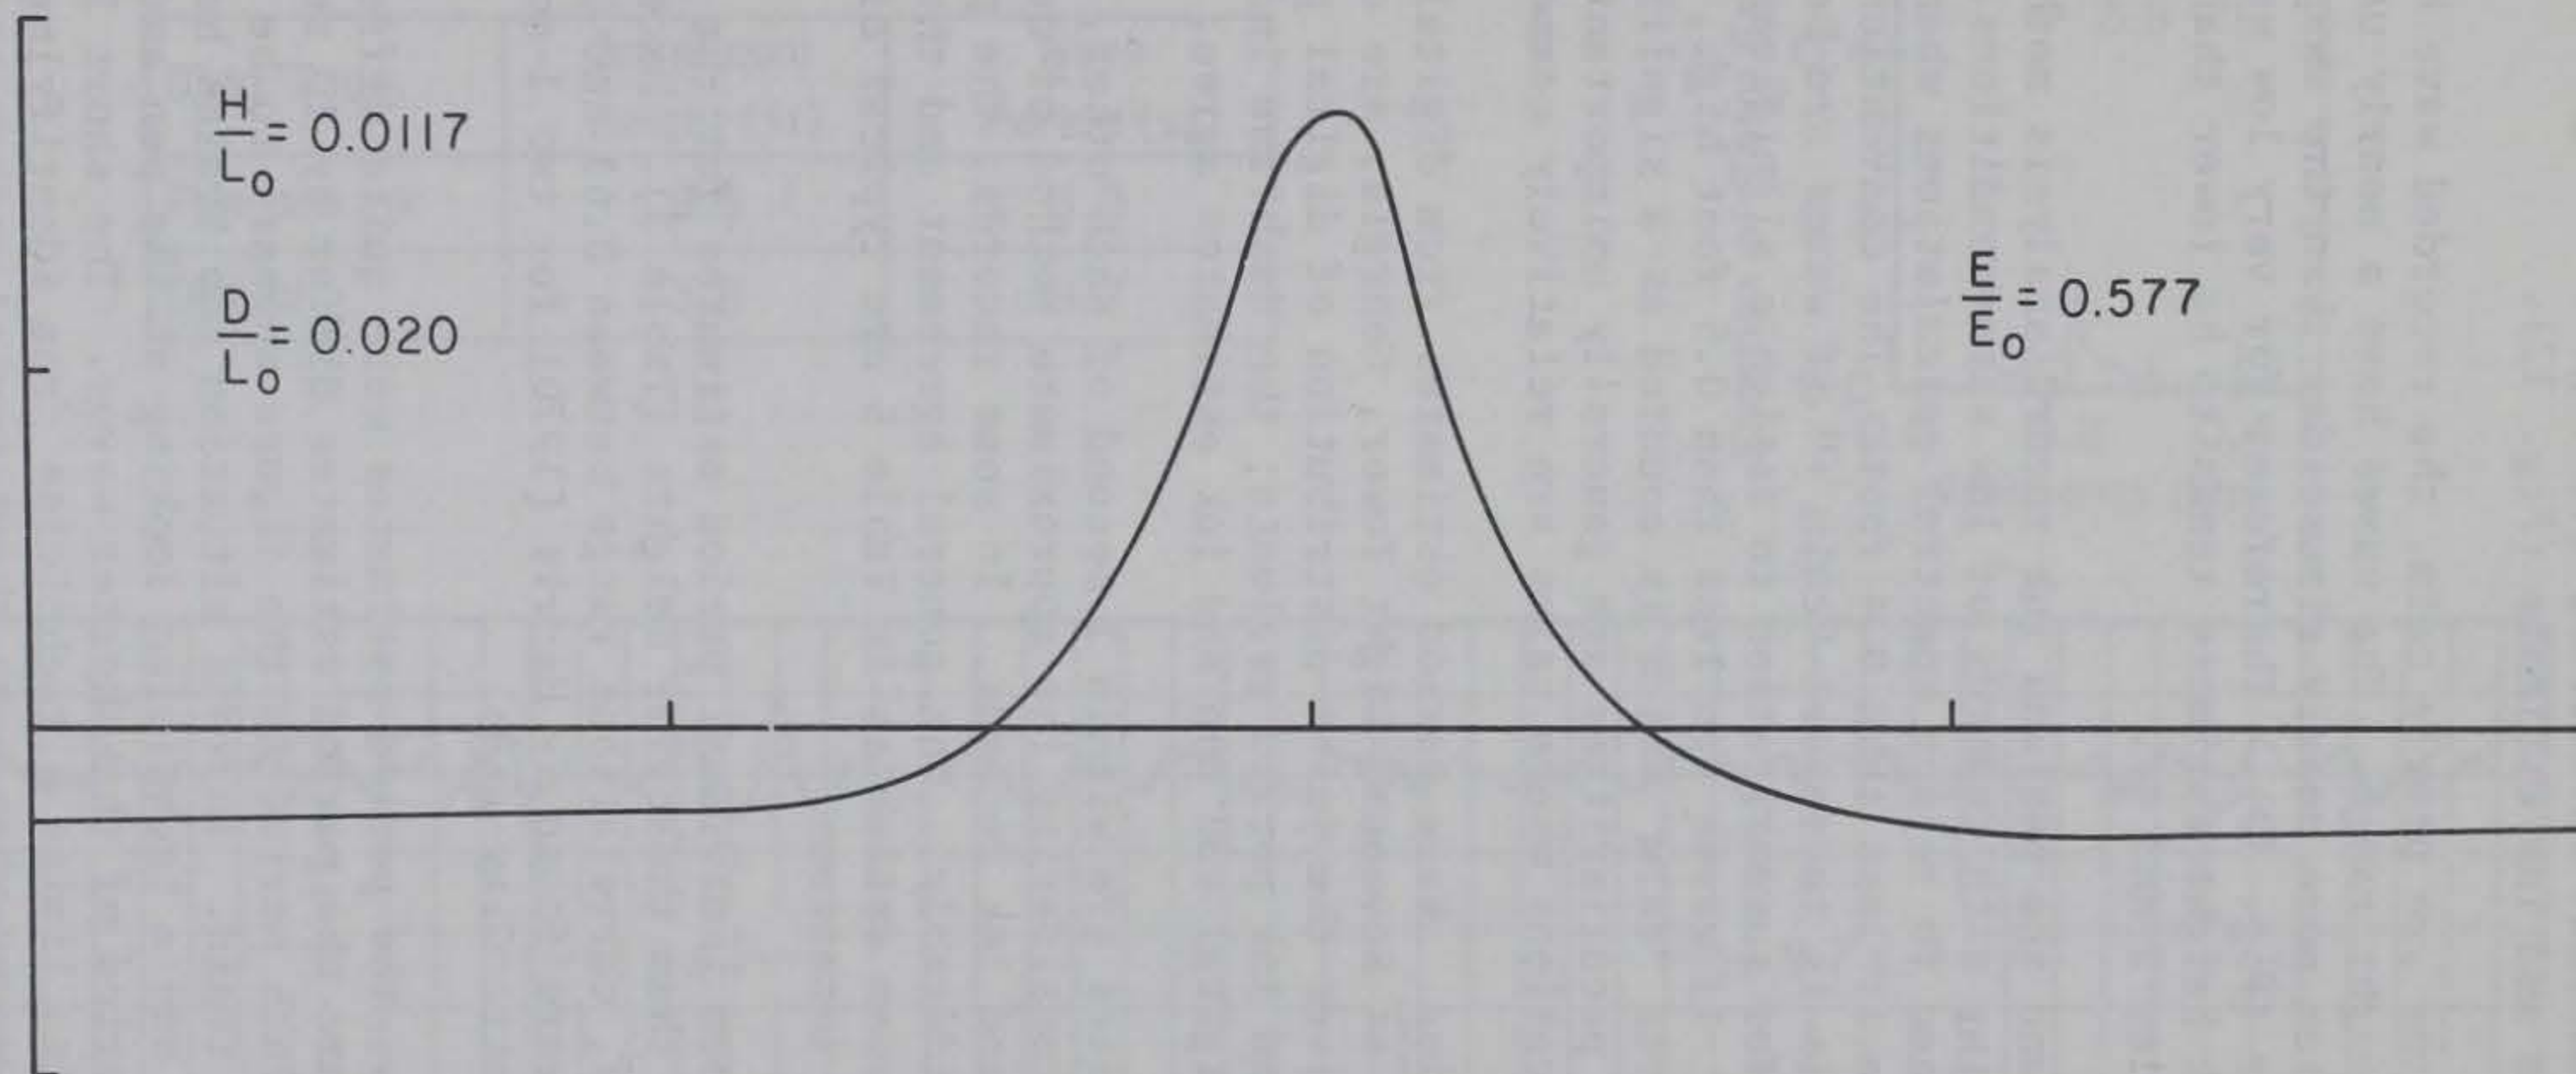

Figure 11. Shallow-water wave profile for $H/L_0 = 0.0117$ and $D/L_0 = 0.010$ (H = wave height, L_0 = deepwater wavelength, and D = water depth). The energy in this wave is equal to 58 percent of the energy in a sinusoidal wave of the same height (Dean, 1974).

percent less than the digital estimate for a purely sinusoidal wave. In practice, when wave conditions indicate relatively uniform heights and approximately sinusoidal waveforms, the digital height estimate may be higher than the pen and ink estimate (Fig. 12).

When wave conditions are nearly calm, the recorded wave heights fall within a very small height range. The waves have a nearly uniform height and their shape is often more nearly sinusoidal than the shape of high waves in shallow water (Fig. 10). Therefore, for very low wave conditions, the pen and ink height estimate tends to be lower than the digital estimate (see Tables 2 and 4).

Both the digital and the pen and ink record analysis methods have peculiarities in dealing with records of low wave conditions. The digital analysis is designed to reject spectral calculations when the significant height estimate is less than 0.4 foot. The convention for pen and ink record analysis is to report "calm +" if waves are between 0.5 and 1 foot high, and for summarization to assign a significant height estimate of 0.7 foot. If waves are less than 0.5 foot high, the pen and ink analysis reports "calm" which is counted as a significant height estimate of 0. These peculiarities are generally unimportant except for records from a few locations where calms are relatively common.

(2) Wave Period. Wave period estimates from digital and pen and ink records taken at Savannah Light Tower, Georgia, are compared in Table 5. The table gives the joint distribution of digital period estimate versus pen and ink period estimate; the dashline indicates the points at which digital and pen and ink estimates agree.

Most period estimates are within 1 second of each other, which is reasonable agreement considering the approximate method of determining wave period from pen and ink records. In some records, the period estimates differ considerably. The general agreement and the occasional large differences between estimates in Table 5 are typical of the records from seven other gage locations.

Correlations between individual period estimates for the full 8-month data sample are lower than those for heights (Table 3). Except for the gage in Chesapeake Bay, correlations range between 0.61 and 0.79. Comparable correlations were found by Harris (1970) for two 1-month data samples from the Atlantic City gage.

In several records, the period estimates were quite different. A pen and ink record where the period estimates differ by 10 seconds is shown in Figure 13. Each period in the figure appears to be associated with a different wave train. In this situation the trains have comparable wave heights, and a technician looking at the pen and ink record usually reports the period of the shorter waves. The short length of pen and ink records also limits a technician from identifying a long-period pattern in the waves when both short-period energy and long-period energy are present.

Data Type	Significant Height (ft)	Wave Period (s)
Pen and Ink	3.5	6.0
Digital	3.8	9.7

Figure 12. Example of wave record from Savannah Light Tower, Georgia, at 0720 hours, 29 May 1972.

Data Type	Significant Height (ft)	Wave Period (s)
Pen and Ink	2.5	4.0
Digital	2.8	14.1

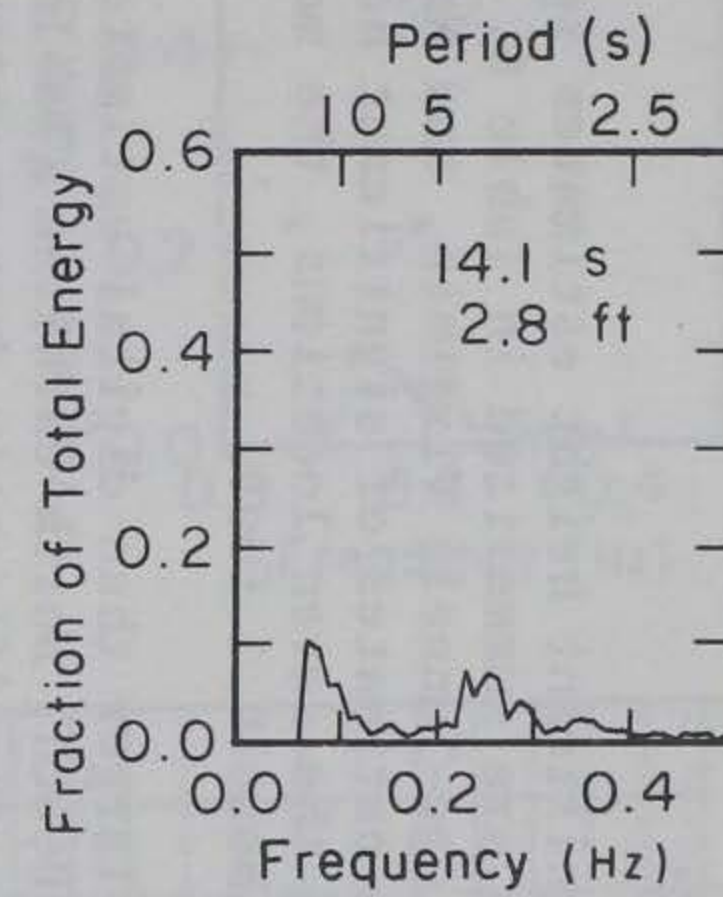

Figure 13. Example of wave record from Savannah Light Tower, Georgia, at 0042 hours, 22 September 1971.

Another pen and ink record (Fig. 14) shows a wave period estimate of 6 seconds and a corresponding digital estimate of 4.5 seconds. Again, the presence of several wave trains appears to be responsible for the discrepancy.

Therefore, much of the scatter in Table 5 can be attributed to the presence of multiple wave trains.

b. Means and Standard Deviations.

(1) Significant Height. Significant height estimates for the full data sample from eight locations are summarized in Table 6. Except for estimates from Chesapeake Bay Bridge-Tunnel, Virginia, and Naples, Florida, mean digital and pen and ink estimates of significant height agree within 10 percent. For four of the seven locations, the mean estimates agree within 4 percent or about 0.1 foot.

Pen and ink height estimates are larger than digital estimates for data from Nags Head and Wrightsville Beach, North Carolina (Table 6). Except for Savannah Light, Georgia, in significantly deeper water, these locations also have the highest mean wave conditions. Thus, the tendency for higher pen and ink estimates is believed due to the nonlinear wave shapes often exhibited by high waves in shallow water as discussed earlier in Section VI, 3,a.

Mean pen and ink height estimates from Chesapeake Bay Bridge-Tunnel and Naples are lower than mean digital estimates (Table 6). The differences are related primarily to the frequent occurrence of relatively calm wave conditions at both locations. For individual pen and ink height estimates which are less than 1 foot, the estimate is usually less than the digital estimate as discussed earlier in Section IV, 3,a. The effect is seen on mean significant height at a location with frequent very low wave conditions. Holden Beach, North Carolina, and Destin, Florida, also have low mean heights, but seldom experience calm conditions.

The engineer is often interested in monthly or seasonal wave conditions at a location. Since the relationship between monthly mean digital and pen and ink height estimates is more variable than mean estimates based on a data sample of several months, the maximum observed difference in monthly mean height estimates for each location is included in Table 6. Most of the maximum differences are less than 20 percent.

Another useful statistic of the distribution function is the standard deviation of significant heights. It is the most important parameter in a simple exponential model of the cumulative distribution function (Thompson and Harris 1972; Harris 1972b; U.S. Army, Corps of Engineers, Coastal Engineering Research Center, 1975, p. 4-35).

The standard deviation of digital significant height estimates and the percentage difference between standard deviations of the digital

Data Type	Significant Height (ft)	Wave Period (s)

¹Digital and pen and ink records were taken within 30 minutes of each other.

² \bar{H}_{DIG} is mean significant height estimate from digital records.

³ \bar{H}_{PI} is mean significant height estimate from pen and ink records.

⁴Months with 70 or more observations were considered.

⁵ σ_{DIG} is standard deviation of significant height estimates from digital records.

⁶ σ_{PI} is standard deviation of significant height estimates from pen and ink records.

⁷Digital estimates were not compensated for hydrodynamic attenuation due to submergence of the gage.

and pen and ink height estimates for each location are included in Table 6. Standard deviations of the pen and ink estimates are between 9 and 33 percent greater in every estimate.

Standard deviations of pen and ink height estimates are high because each estimate is based on only a few of the higher waves in a 7-minute record; each digital estimate is based on a full 1,024-second record. Thus, the pen and ink estimates would be expected to show more scatter, and also the tendency for pen and ink estimates to be relatively high for high waves in shallow water leads to larger standard deviations of the estimates.

(2) Wave Period. Wave period estimates for all eight locations are summarized in Table 7. At each location, the mean pen and ink estimate is lower than the mean digital estimate; however, the differences are small, about one-half a second or less.

Differences between observed monthly mean period estimates are greater, although the pen and ink estimates are never more than 1 second or 15 percent less than the digital estimates. This tendency for pen and ink period estimates to be lower than digital estimates was discussed previously.

The standard deviation of wave period estimates at each location (Table 7) is between 6 and 40 percent smaller for pen and ink estimates than for digital estimates.

c. Distribution Functions. Since many engineering applications of wave data require a distribution function giving the frequency of occurrence of height or period estimates in specified intervals, a comparison of distribution functions from digital and pen and ink estimates is warranted.

Distribution functions of significant height estimates for two locations are plotted in Figure 15. The figure shows that the pen and ink analysis gives more height estimates in the highest intervals of the distribution function, as expected from previous discussion of high waves in shallow water (a characteristic which is particularly noticeable for Wrightsville Beach in Fig. 15,b).

The pen and ink analysis also gives an excessive number of heights in the lowest interval of the distribution function. This characteristic can be attributed to the instructions for the record analysis which state that records with all waves lower than 1 foot be reported as "calm +" or "calm". Since this procedure is simpler than that for records with waves higher than 1 foot, the analyzer tends to facilitate the job by reporting marginal cases as "calm +".

The situation is reversed for wave period estimates. Digital period estimates are more common than pen and ink estimates at both the high and low ends of the distribution function (Fig. 16). Discontinuities

in the distribution functions for digital estimates are due to the low resolution of the digital analysis for long wave periods (see Section V).

The tendency of pen and ink period estimates to be shorter than digital estimates was discussed earlier in this section (VI, 3,a). The scarcity of pen and ink estimates at the other end of the distribution function is partially due to the subjectivity of the analysis. Since multiple wave trains are common, a technician analyzing pen and ink records often has several alternative wave periods to report, and when given a choice, usually favors wave periods close to the overall mean.

4. Summary of Comparisons between Simultaneous Digital and Pen and Ink Records.

Comparisons of digital and pen and ink records taken within 30 minutes of each other are summarized below.

(a) Individual significant wave height estimates agree within ± 10 percent one-half the time, but occasionally differ by ± 40 percent or more.

(b) Individual wave period estimates generally agree within ± 1 second, but can differ by 10 seconds if several wave trains are present.

(c) Mean significant height estimates generally agree within 10 percent or less; standard deviations of height estimates based on pen and ink data are about 20 percent greater than those based on digital data.

(d) Mean wave period estimates from pen and ink data are about 10 percent less than period estimates from digital data; standard deviations are about 20 percent smaller than those based on digital data.

(e) Pen and ink estimates generally give more heights at the upper and lower extremes than digital estimates.

(f) Pen and ink estimates generally give fewer periods at the upper and lower extremes than digital estimates.

VII. COMPARISON OF WAVE CLIMATE FROM DIGITAL AND PEN AND INK RECORDS

Although digital and pen and ink wave records taken within 30 minutes of each other during an 8-month period generally give comparable estimates of significant wave height and period, it is also important to compare wave climate determined from a large sample of both types of data. If these data indicate basically the same wave climate at locations where both types are available, both digital and pen and ink estimates can be used with confidence in determining wave climate at other locations.

Thompson and Harris (1972) showed that the cumulative distribution function of significant wave height for a full year of data is generally characteristic of a location for the lower 99 percent of the significant waves. This is supported by the more recent and complete years of data included in Appendix A. Large wave heights can vary from year to year; however, except for extremes, a year of data will provide a good sampling of local meteorological conditions and the waves they generate. Thompson and Harris also indicated that the annual distribution function of significant height is independent of the time of day when the data were collected. Thus, to check the climatological validity of significant height estimates, annual summaries are desirable.

Annual means and standard deviations of significant height estimates are plotted in Figure 17 for most reasonably complete years of data included in Appendix A. Most differences between annual mean significant height estimates for the same data type from different years are as great as differences between annual means for different data types. Except for Huntington Beach, California, estimates of annual mean significant height are within about 30 percent or 1 foot of each other, and differences at most locations can be attributed to annual variability in wave conditions. The pen and ink estimates for Huntington Beach differ substantially from the digital estimates due to the old design of the gage at Huntington Beach before July 1969 and to the difficulty of maintaining a gage located so far from BEB-CERC.

Most annual standard deviations of significant height estimates from digital and pen and ink data compare favorably (Fig. 17).

Annual means and standard deviations of significant period estimates are plotted in Figure 18. Annual mean pen and ink period estimates are slightly lower than the digital estimates, although both estimates are generally within 15 percent or 1 second of each other. Standard deviations of period estimates are also comparable, generally differing by less than 30 percent.

Annual distribution functions of significant height estimates can conveniently be compared when plotted in a semilog format (Thompson and Harris, 1972; Harris, 1972b). BEB-CERC data for seven different locations are sufficient to permit such comparisons between digital and pen and ink estimates. The comparisons are best illustrated in Appendix A which summarizes data from Atlantic City, New Jersey, Virginia Beach, Virginia, Nags Head, North Carolina, Naples, Florida, and Huntington Beach, California. Data in the appendix for each of these locations show that, for the more recent and complete years of data, the annual variability in the distribution function of significant height estimates from one data type is as great as the variations between distribution functions from different data types. For Huntington Beach, the distribution functions from digital data are higher than distribution functions from pen and ink data for reasons noted earlier in this section.

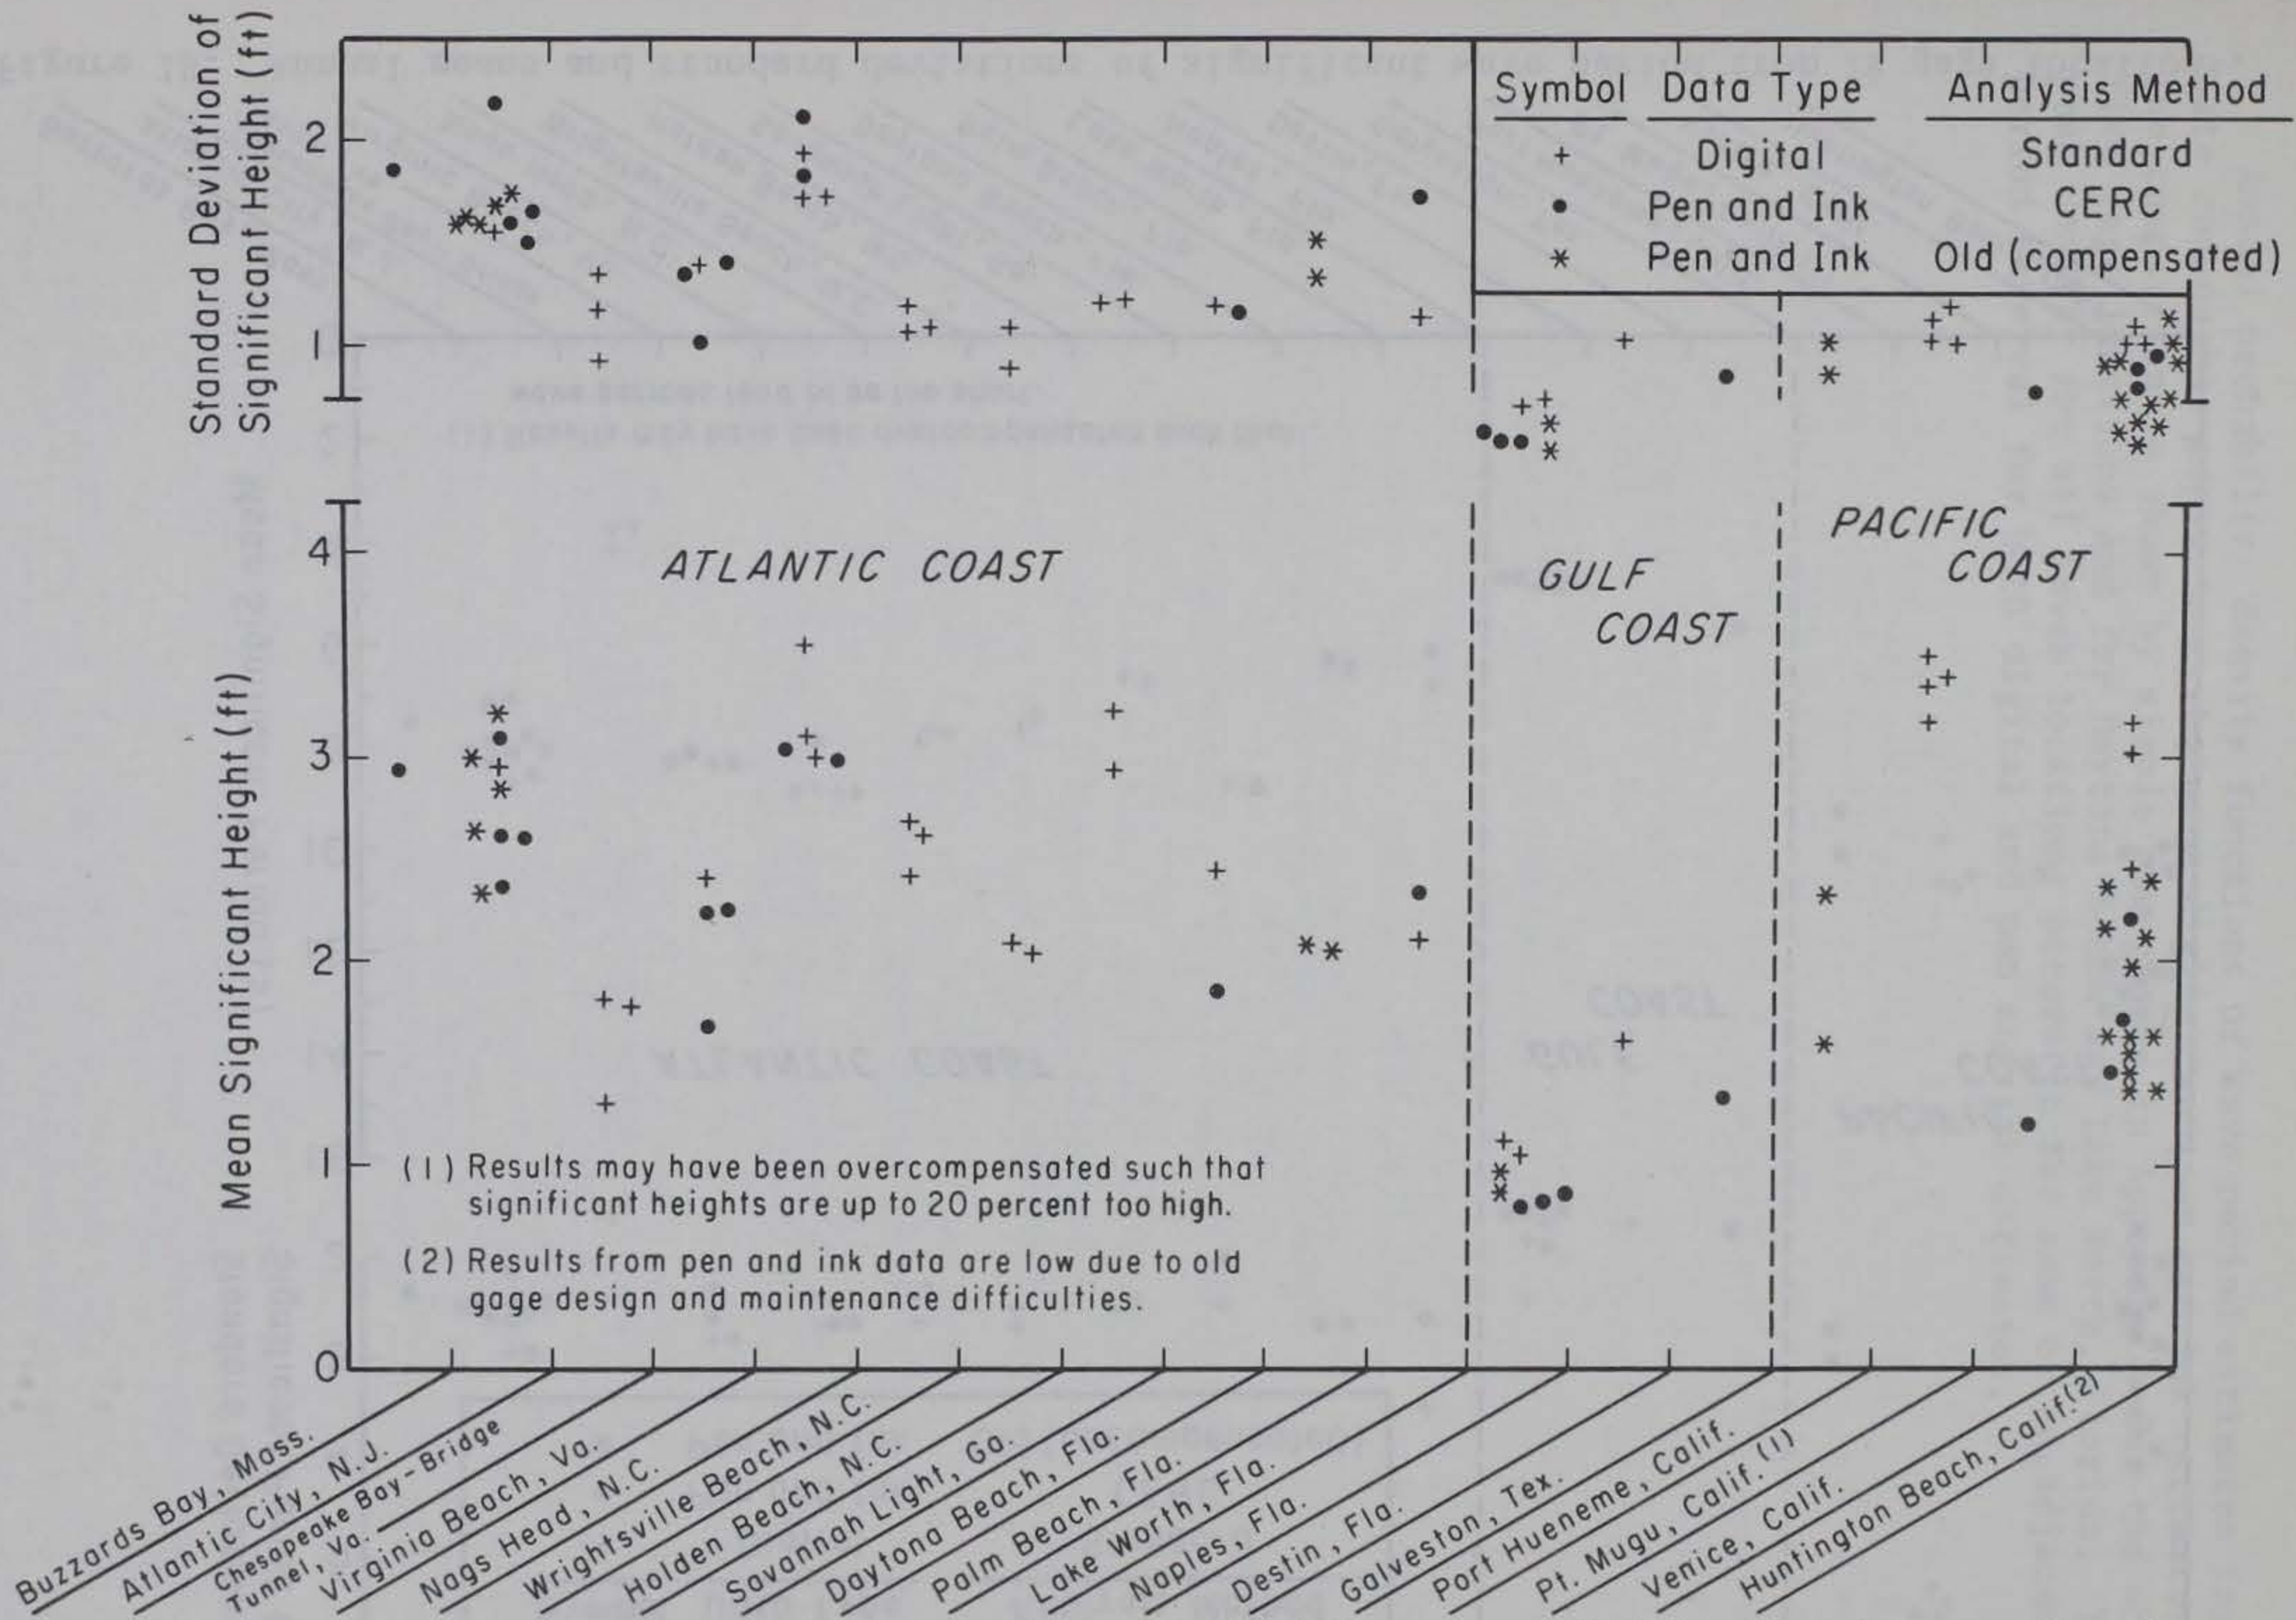

Figure 17. Annual means and standard deviations of significant wave height from 19 gage locations.

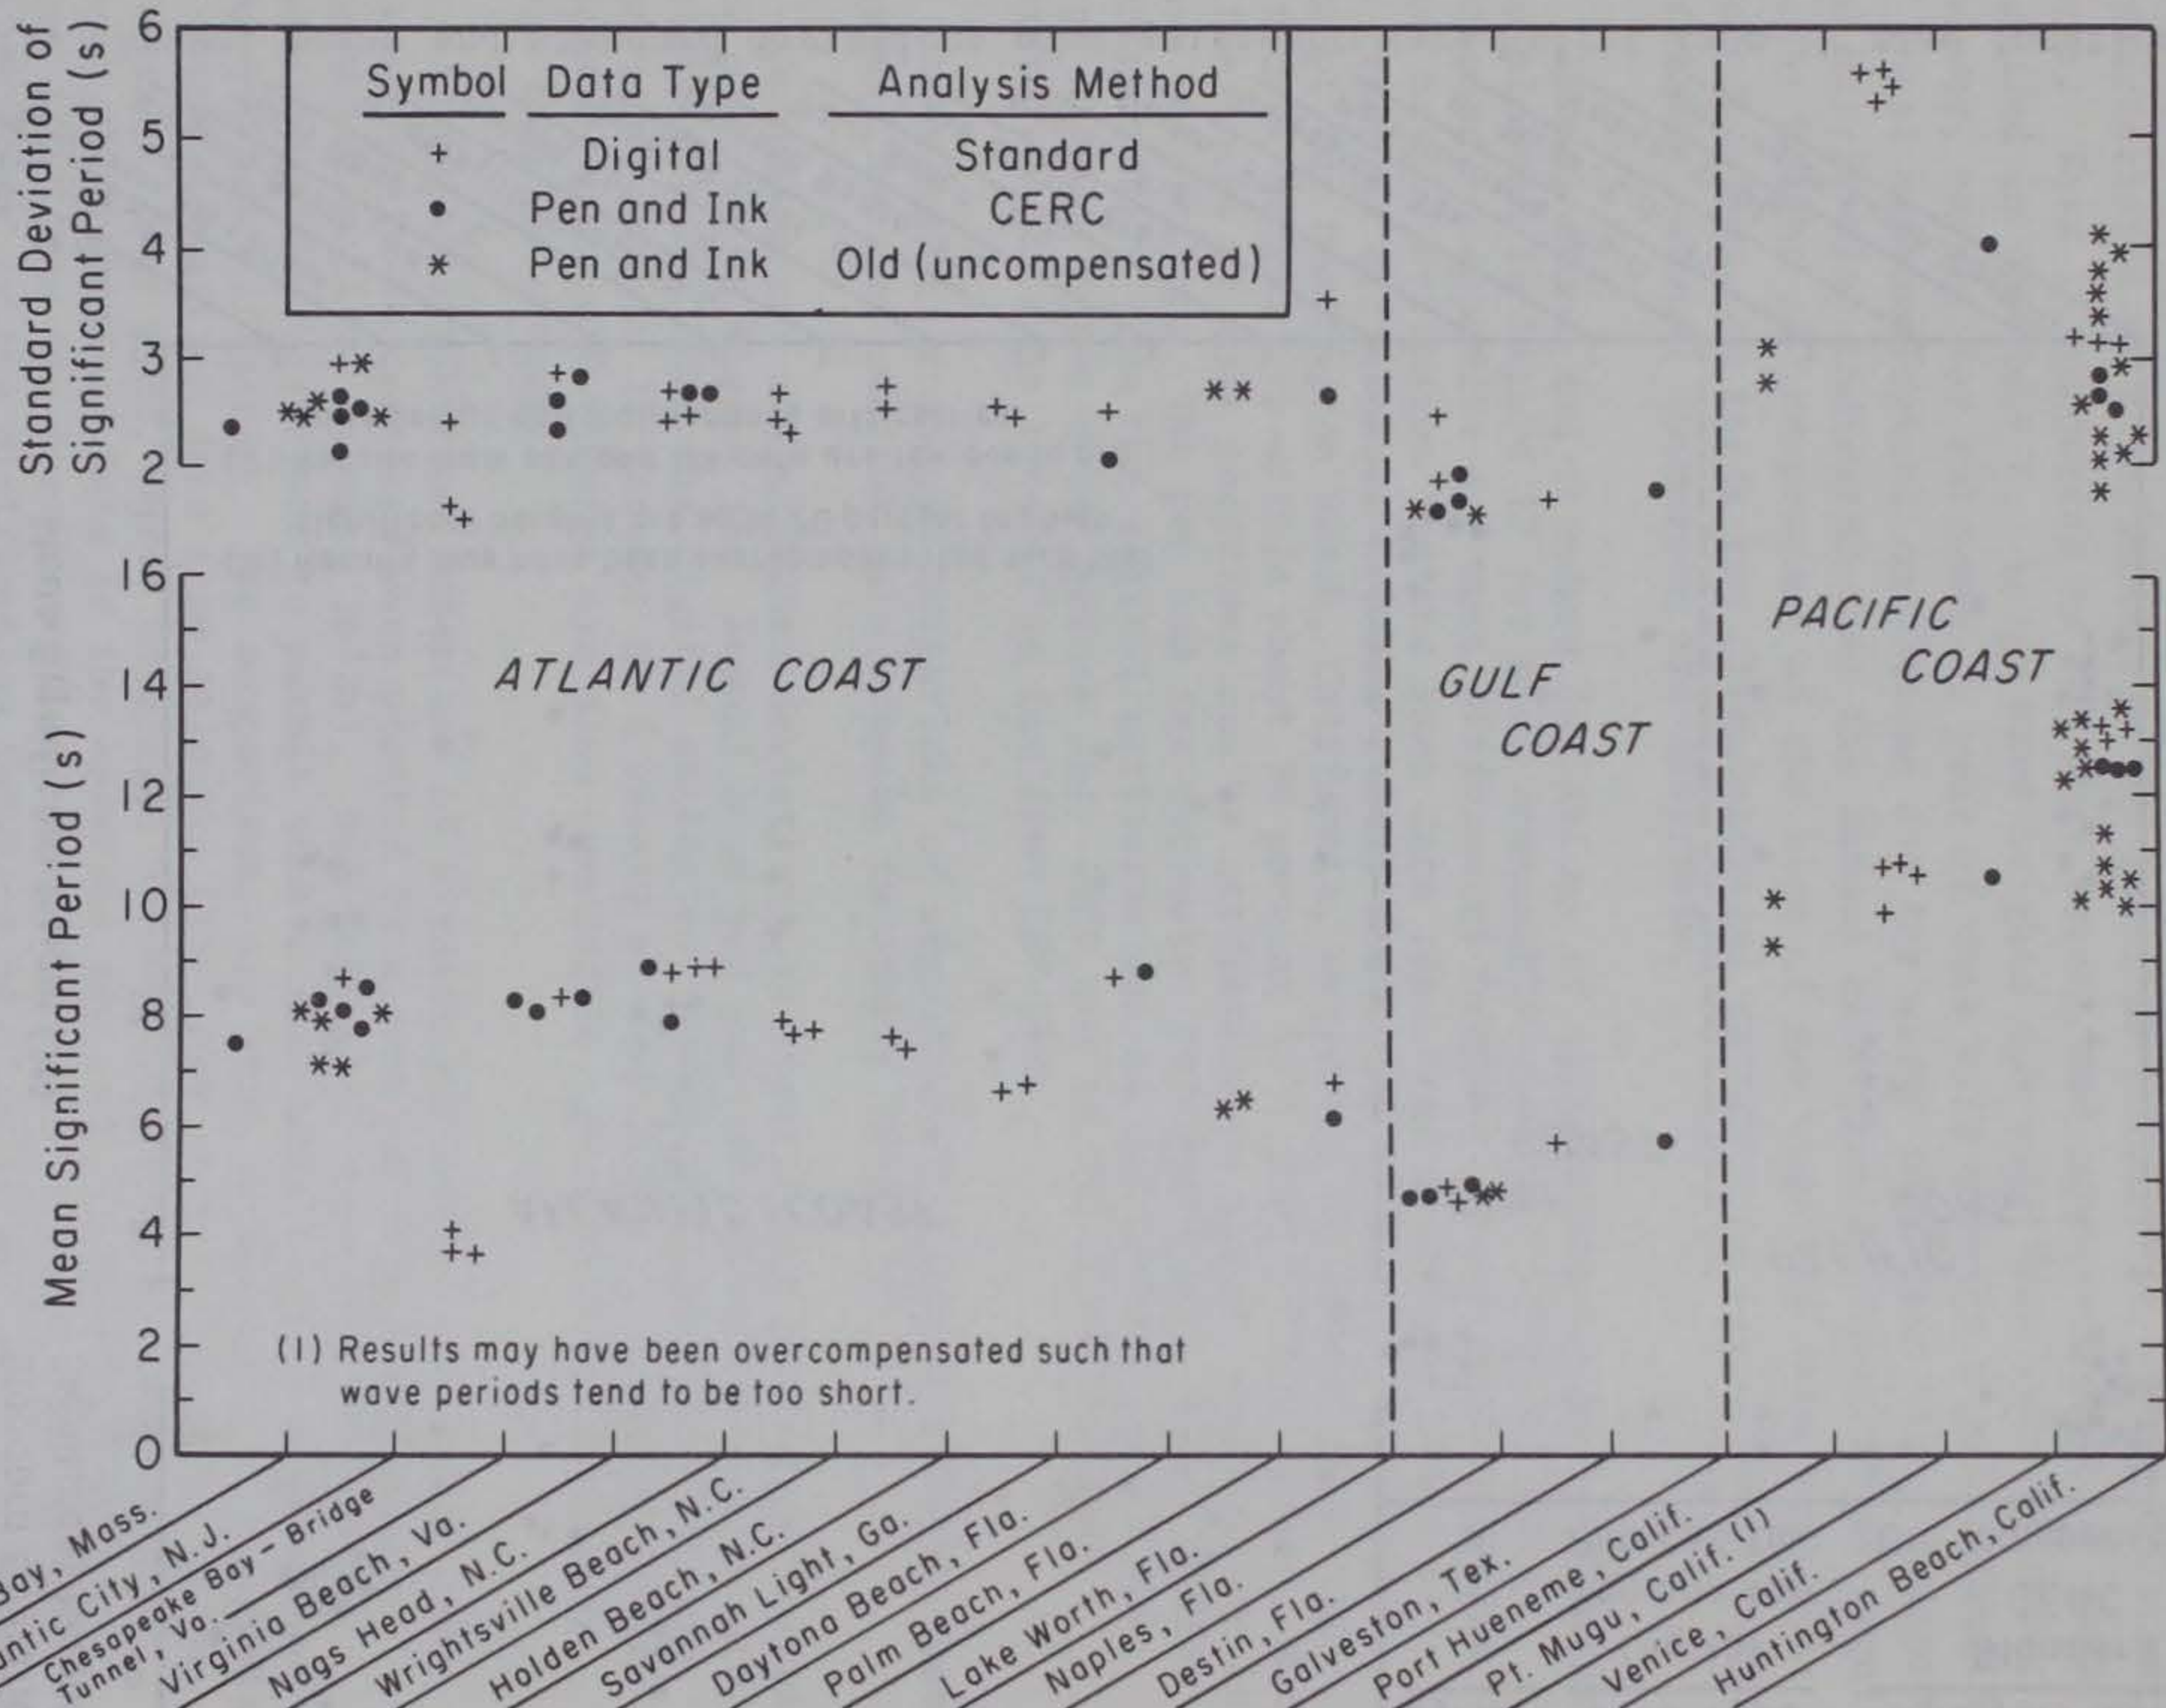

Figure 18. Annual means and standard deviations of significant wave period from 19 gage locations.

Annual probability density functions of wave period estimates indicate reasonable consistency between digital and pen and ink estimates. The comparison is shown by simple bar graphs in Appendix A for the above five gage locations and for Daytona Beach and Lake Worth, Florida. The peak density for all seven locations occurs in the same or an adjacent period interval for both digital and pen and ink estimates.

APPENDIX A

EXPLANATION OF SUMMARIES OF SIGNIFICANT HEIGHT AND PERIOD

1. General Format of Summaries.

Significant heights and periods are summarized in Appendixes A-1 (U.S. Atlantic coast gages), A-2 (gulf coast gages), and A-3 (Pacific coast gages). Each appendix includes a map showing gage locations. The data summaries are ordered according to gage location, from north to south for the oceanic coasts and from east to west for the gulf coast.

The following data are included in the summaries for each location:

- (a) Gage history;
- (b) number of records analyzed for each month and year;
- (c) plot of monthly maxima, means, and standard deviations of significant height;
- (d) plot of monthly means and standard deviations of significant period;
- (e) plot of annual significant height distribution functions;
- (f) plot of annual significant period distribution functions;
- (g) plot of seasonal significant height distribution functions; and
- (h) seasonal and total joint distribution functions of significant height versus period.

2. Explanation of Summary Formats.

a. Gage Histories. A tabular history of the wave gage or gages which acquired the data is included in the summaries. The history includes pertinent physical information about the gage, the gage supporting structure, and dates for wave records obtained with no continuous interruptions longer than 1 month. Some of the interruptions are documented and explained, but many short interruptions in the recording sequence are not mentioned.

b. Number of Analyzed Records. The number of analyzed wave records available for each month and year is presented in each appendix. Since pen and ink records taken before 1971 were made at 4-hour intervals, the maximum number of pen and ink record analyses in a 30-day month was 180; the maximum number of analyses in a 365-day year was 2,190. Recent

digital records have been analyzed at 6-hour intervals; therefore, the maximum number of digital analyses in a 30-day month is 120, and in a 365-day year is 1,460.

c. Monthly Maxima, Means, and Standard Deviations of Significant Height. Plots of monthly significant height statistics are included as figures in each appendix. Monthly means, identified by year and data type, are plotted for the recent and reliable data from each location. The range of monthly standard deviations obtained for each month of the year is also shown. Means and standard deviations are included only for months with 100 or more analyzed pen and ink records or 60 or more digital records.

The maximum significant height obtained for each month of the year is also shown in the plots. In several cases two maxima are plotted for each month, one maximum for digital analyses and one maximum for pen and ink record analyses.

Annual means and standard deviations of significant height are plotted at the right-hand edge of the figures for the more reliable and complete years of data. A complete plot of annual height statistics is given in Figure 17 of the text.

The data for Palm Beach and Port Hueneme were obtained by an old method of pen and ink record analysis and have been compensated to compare with data obtained by recent analysis methods (the compensation procedure is discussed later in this section).

d. Monthly Means and Standard Deviations of Significant Period. Each appendix contains figures of monthly significant period statistics. Monthly mean significant periods and the range of monthly standard deviations are plotted for the same months and in the same format as the significant height statistics. Annual significant period statistics are also included for the more reliable and complete years of data. A complete plot of annual period statistics is given in Figure 18 of the text.

e. Annual Significant Height Distribution Functions. Semilog plots of annual cumulative distribution functions of significant wave height are included as figures in the appendixes. At locations where more than 4 years of data are available, the distribution functions are plotted in clusters of from one to four curves, with the origin for each successive cluster spaced 5 scale meters above the previous origin. A distribution function corresponding to a relatively complete year of data is represented by a dashline common to all clusters. Distribution functions derived from both digital and pen and ink data are included in the plots.

In most years with less than 1,600 analyzed pen and ink records at 6 per day or less than 700 analyzed digital records at 4 per day, annual significant height distribution functions have been omitted. These cut-offs, discounting years of pen and ink results less than 73 percent

complete and years of digital results less than 48 percent complete, were chosen arbitrarily after examination of the data. A lenient cut-off for digital analyses seems justified since a digital estimate of significant height is more reliable than a pen and ink estimate, and gaps in the digital analyses are often unrelated to wave conditions.

The number of analyzed records in each year is listed within the boundaries of the plot. The plot for Pt. Conception, California, has been omitted because insufficient analyses were available to provide a meaningful annual distribution function of significant wave heights.

Some of the data for Atlantic City, Palm Beach, Naples, Port Hueneme, and Huntington Beach were obtained by an old method of pen and ink record analysis, and compensated to compare with data obtained by recent analysis methods (the compensation procedure is discussed later in this section).

f. Annual Significant Period Distribution Functions. Bar graphs of annual distribution functions of significant wave period obtained by the most reliable analysis method, preferably digital analysis, are presented in each appendix. Many of the graphs indicate the range of percentages in each interval obtained by an older, less reliable analysis method.

The median period for Atlantic coast gages is generally 8 to 9 seconds, although the number of wave periods occurring in the 8- to 9-second interval is exaggerated by the digital analysis (see Section V). For gulf coast gages, the median period ranges between 2 and 6 seconds; for Pacific coast gages, the median period is generally 14 to 15 seconds.

The figure for Pt. Conception has been omitted because of insufficient data.

g. Seasonal Significant Height Distribution Functions. Figures showing seasonal cumulative distribution functions of significant height for several individual months combined are included in each appendix. The distribution functions represent only data from months with 100 or more analyzed pen and ink records or 60 or more digital records, except in several months where insufficient data were available. The distribution functions also represent analyses from one homogeneous data source: Digital data, pen and ink data analyzed by the CERC method, or, for Palm Beach and Port Hueneme, pen and ink data analyzed by old BEB methods and suitably compensated by regression equations (the compensation procedure is discussed later in this section).

h. Joint Distribution Functions of Significant Height versus Period. Tables in most of the appendixes contain 13 tabular joint distribution functions of significant height and period. Results are summarized by months with 60 or more digital records or 100 or more pen and ink records. Each table summarizes monthly results from 1 to 4 years derived from a homogeneous data source: Digital data, pen and ink data analyzed by the CERC method, or, for Palm Beach and Port Hueneme, pen and ink data

analyzed by old BEB methods, with heights suitably compensated by regression equations (discussed later). The monthly tables of joint distribution functions are followed by a single table summarizing all monthly data.

For locations with sizable quantities of both digital and pen and ink data, results are summarized from the more abundant source as discussed above. Results from the less abundant source are summarized in an additional table for use in evaluating extreme conditions.

Each table indicates the months and years and the total number of observations represented. The main body of the table gives the number of observations for which the significant height and period were within the specified intervals. All numbers in the interior of the table have been normalized to give the number of observations per 1,000 observations. These numbers can be converted to percent by dividing by 10.

Marginal totals are also included. The row labeled "Total" gives the total number of observations out of 1,000 which fell within each specified significant height interval. The column total gives the number of observations out of 1,000 which fell within each specified period interval. Observations in the lowest period interval usually represent calm conditions, but were not considered in normalizing the column totals. The cumulative totals in the tables are totals of the entries in the "Total" row and column.

Each entry in the "Row Average" column gives the average significant height for all observations within a specified period interval. Entries under "Column Average" are the average significant period for all observations within a specified height interval. The row and column averages are useful for investigating the relationship between significant height and period. For most ocean coastal locations the largest significant heights are usually associated with intermediate periods. However, the tables show no consistent simple relationship between significant height and period. A tendency for significant period to increase with increasing significant height is apparent for gulf coast and Chesapeake Bay locations.

At the bottom of each table is a list of the average, variance, and standard deviation of both significant heights and significant periods. The type of data and gage used to obtain the data summarized in the table along with other remarks are footnoted.

i. Compensation for Different Pen and Ink Analysis Methods. Results obtained by the older, less reliable methods of pen and ink record analysis discussed in Section IV are included for several locations. These results are grouped into relatively homogeneous blocks according to the method of analysis and the person performing the analysis.

For Atlantic City, Palm Beach, and Huntington Beach, a 1- to 2-month sample of pen and ink records from each block was reanalyzed with the

CERC method. For each sample, a linear regression equation was computed for significant height estimates obtained by the two methods and for significant period estimates. Where necessary, the appropriate regression equation was applied to significant wave height statistics obtained by the old methods of analysis. Regression equations from the above locations were applied to data from Virginia Beach, Naples, and Port Hueneme to compensate old significant wave height statistics.

Significant wave period statistics obtained by the old methods of pen and ink record analysis are included for Palm Beach and Port Hueneme, but have not been compensated.

Details of the compensation for each location are included in a table.

j. Time History of Significant Height and Period. Figures for an east coast location (Atlantic City) and a west coast location (Huntington Beach), are included in the appendixes to give perspective on the time history of significant height and period during 4 months of high wave activity.

k. Monthly Significant Height Distribution Functions. Each curve in the plots of seasonal significant height distribution functions represents an average of from 1 to 4 months. A number of plotted monthly significant height distribution functions are included in the appendixes for Atlantic City and Huntington Beach. The monthly distribution functions are plotted in the standard format and show trends toward high or low wave conditions in some months, but also show considerable variability for different years. The plots do not include the number of analyzed records for each month; however, the number can be determined from the tables listing the number of analyzed records for each month and year.

APPENDIX A-1

SIGNIFICANT WAVE HEIGHT AND PERIOD SUMMARIES, U.S. ATLANTIC COAST

¹Results before November 1968 obtained from 7-minute pen and ink records taken six times daily; analyzed by the second BEB for 1957 to March 1964 and by the CERC method for April 1964 to 1967. Results after November 1968 obtained from 1,024-second digital records taken four times daily.

Figure A-7. Maxima, means, and standard deviations of significant height from Atlantic City, New Jersey.

Figure A-8. Means and standard deviations of wave periods for Atlantic City, New Jersey.

NOTE:

+ = computed from 1,024-second digital wave records taken four times daily.

* = determined by an old analysis method from 7-minute pen and ink records taken six times daily and compensated to compare with results from recent analysis methods (see Tables A-7 and A-8).

Unmarked = determined from 7-minute pen and ink records taken six times daily.

Figure A-9. Annual cumulative significant height distributions from Atlantic City, New Jersey.

Figure A-10. Annual significant period distributions from Atlantic City, New Jersey.

Figure A-11. Seasonal summaries of cumulative significant height distributions from Atlantic City, New Jersey; determined from 7-minute pen and ink records taken six times daily.

Table A-6. Wave climate for Atlantic City, New Jersey.
 Distribution of significant height versus period
 (in observations per 1,000 observations).

RESULTS OBTAINED FROM 1024-SECOND DIGITAL RECORDS TAKEN WITH A STEP RESISTANCE RELAY
 WAVE GAGE LOCATED AT STEEL PIER.
 * CALMS ARE OMITTED.

Table A-7. Comparison of results from different pen and ink wave record analysis methods, Atlantic City, New Jersey.

Dates of data sample reanalyzed by CERC method	Significant heights ¹			Significant periods ²		
	Correlation between heights	A (ft)	B	Correlation between periods	C (s)	D
Oct. to Nov. 1958	0.93	0.47	0.91	0.87	1.68	0.79
Oct. to Nov. 1961	0.88	0.12	0.81	0.66	1.90	0.73
Oct. 1961	0.88	0.19	0.80	0.62	2.87	0.64
Nov. 1961	0.88	0.03	0.83	0.69	1.13	0.79
Jan. to Feb. 1964	0.93	0.23	0.76	0.74	1.37	0.76
Jan. 1964	0.94	0.23	0.76	0.85	1.59	0.76
Feb. 1964	0.91	0.23	0.76	0.67	1.13	0.77

¹Significant height from CERC method
= A + B × (significant height from old method).

²Significant period from CERC method
= C + D × (significant period from old method).

Table A-8. Regression equations used to compensate significant height statistics for Atlantic City, New Jersey.

Date	Compensation equations (ft)
1958 to 1959	$H_{NEW} = 0.47 + 0.91 H_{OLD}$
1960 to Mar. 1964	$H_{NEW} = 0.17 + 0.79 H_{OLD}$
Apr. 1964 to 1971	No compensation

NOTE:

H_{NEW} = estimate of significant height that would have been obtained by the CERC method of pen and ink record analysis.

H_{OLD} = significant height obtained by old method of pen and ink record analysis.

1969	111	107	101	85	84	56	121	121	104	59			949

¹Results before November 1968 obtained from 7-minute pen and ink records taken six times daily; analyzed by the second BEB method for 1962 to March 1964 and analyzed by the CERC method for April 1964 to June 1968. Results after November 1968 obtained from 1,024-second digital records taken four times daily.

Figure A-23. Maxima, means, and standard deviations of significant height from Virginia Beach, Virginia.

Figure A-24. Means and standard deviations of wave periods for Virginia Beach, Virginia.

NOTE:

+ = computed from 1,024-second digital wave records taken four times daily.

Unmarked = determined from 7-minute pen and ink records taken six times daily.

 WAVE GAGE LOCATED AT 15TH STREET PIER.
 * CALMS ARE OMITTED.

Table 15. Regression equations used to compensate significant height statistics for Virginia Beach, Virginia.

Date	Compensation equations (ft)
1962 to Mar. 1964	$H_{NEW} = 0.23 + 0.76 H_{OLD}$
Apr. 1964 to 1968	No compensation

NOTE:

H_{NEW} = estimate of significant height that would have been obtained by the CERC method of pen and ink record analysis (based on reanalysis of 2 months of data from Atlantic City, New Jersey).

H_{OLD} = significant height obtained by old method of pen and ink record analysis.

Table A-16. CERC wave gage history for Jennettes Fishing Pier, Nags Head, North Carolina.

CERC Form 174-74 18 Mar 74								
COORDINATES: 35°55' N., 75°36' W.				LOCATION: Jennettes Fishing Pier, Nags Head, North Carolina				
Type of Gage	Beginning of Proper Operation	End of Proper Operation	Explanation	Gage Length (feet)	Gage Range (ft MSL)	Water Depth (ft MSL)	Distance from seaward end of pier	Pier Length (feet)
Step-resistance, staff-relay type	8 Oct. 1963	9 July 1964	Recorder struck by lightning.	25	-7 to +18	17	153 ft (on north side of pier)	750
	21 July 1964	28 May 1965	Gage struck by lightning.					
	13 June 1965	29 July 1966	Gage struck by lightning.					
	9 Aug. 1966	1 July 1971	Gage struck by lightning.					
	28 Aug. 1971	6 July 1972	Electronic trouble.					
Continuous-wire staff	7 Aug. 1972	31 Oct. 1972	New gage installed.	25	-8 to +17	17	153 ft (on north side of pier)	750
	3 Nov. 1972	29 May 1973	Pier damaged by storm.					
	15 Mar. 1974	10 May 1974	Gage struck by lightning.					
	13 June 1974	23 June 1974	Gage struck by lightning.					
	27 Aug. 1974	17 Oct. 1974	Gage struck by lightning.					
	14 Nov. 1974		Still operative as of 1 Feb. 1975.

¹Results before November 1968 obtained from 7-minute pen and ink records taken six times daily; analyzed by the CERC method. Results after November 1968 obtained from 1,024-second digital records taken four times daily. Results for September 1971 to December 1972 have not been compensated for hydrodynamic attenuation due to submergence of the gage.

Figure A-48. Maxima, means, and standard deviations of significant height from Daytona Beach, Florida.

Figure A-49. Means and standard deviations of wave periods for Daytona Beach, Florida.

NOTE:

+ = computed from 1,024-second digital wave records taken four times daily.

Unmarked = determined from 7-minute pen and ink records taken six times daily.

 STANDARD DEVIATION OF HEIGHT = 1.43 FT STANDARD DEVIATION OF PERIOD = 2.67 SEC*

RESULTS OBTAINED FROM 7-MINUTE PEN AND INK RECORDS TAKEN WITH A STEP RESISTENCE
 WAVE GAGE LOCATED AT PALM BEACH PIER
 * CALMS ARE OMITTED.

Table A-34. Comparison of results from different pen and ink wave record analysis methods, Palm Beach, Florida.

Dates of data sample reanalyzed by CERC method	Significant heights ¹			Significant periods ²		
	Correlation between heights	A (ft)	B	Correlation between periods	C (s)	D
Feb. 1960	0.91	0.04	0.81	0.77	1.07	0.83

¹Significant height from the CERC method
 = $A + B \times$ (significant height from old method).

²Significant period from the CERC method
 = $C + D \times$ (significant period from old method).

Table A-35. Regression equations used to compensate significant height statistics for Palm Beach, Florida.

Year	Compensation equations (ft)
1959 to 1962	$H_{NEW} = 0.04 + 0.81 H_{OLD}$

NOTE:

H_{NEW} = estimate of significant height that would have been obtained by the CERC method of pen and ink record analysis.

H_{OLD} = significant height obtained by old method of pen and ink record analysis.

Table A-36. CERC wave gage history for Lake Worth Municipal Fishing Pier, Lake Worth, Florida.

CERC Form 174-74 18 Mar 74								
COORDINATES: 26°37' N., 80°02' W.				LOCATION: Lake Worth Municipal Fishing Pier, Lake Worth, Florida				
Type of Gage	Beginning of Proper Operation	End of Proper Operation	Explanation	Gage Length (feet)	Gage Range (ft MSL)	Water Depth (ft MSL)	Distance from seaward end of pier	Pier Length (feet)
Step-resistance, staff-relay type	20 Jan. 1966	27 May 1971	Gage removed; pier being rebuilt.	20	-5 to +15	18	0 (on north side side of pier)	800
Continuous-wire staff	22 Jan. 1973	11 Feb. 1973	Gage damaged by storm.	20	-5 to +15	18	0	800
Continuous-wire staff	3 Aug. 1973	24 Aug. 1973	Electronics not working properly.	20	-5 to +15	18	0	800
	14 Nov. 1973	22 Feb. 1974	Electronics not working properly.					
	1 June 1974	14 June 1974	Gage struck by lightning.					
	20 Sept. 1974	1 Oct. 1974	Gage struck by lightning.					
	11 Oct. 1974	18 Mar. 1975	Gage discontinued.

¹Results before November 1968 obtained from 7-minute pen and ink records taken six times daily; analyzed by the second BEB method for 1957 to March 1964 and analyzed by the CERC method for April 1964 to 1967. Results after November 1968 obtained from 1,024-second digital records taken four times daily.

Figure A-64. Maxima, means, and standard deviations of significant height from Naples, Florida.

Figure A-65. Means and standard deviations of wave periods for Naples, Florida.

NOTE:

+ = computed from 1,024-second digital wave records taken four times daily.

* = determined by an old analysis method from 7-minute pen and ink records taken six times daily and compensated to compare with results from recent analysis methods (see Table A-42).

Unmarked = determined from 7-minute pen and ink records taken six times daily.

Figure A-66. Annual cumulative significant height distributions from Naples, Florida.

Figure A-67. Annual significant period distributions from Naples, Florida.

NOTE:

+ = computed from 1,024-second digital wave records taken four times daily.

Figure A-68. Seasonal summaries of cumulative significant height distributions from Naples, Florida; computed from 1,024-second digital wave records taken four times daily.

RESULTS OBTAINED FROM 7-MINUTE PEN AND INK RECORDS TAKEN WITH A 8YEP RESISTANCE
 WAVE GAGE LOCATED NEAR VENTURA COUNTY HARBOR
 * CALMS ARE OMITTED.

Wave heights may be low due to old gage design and maintenance difficulties.

Table A-55. Regression equations used to compensate significant height statistics for Port Hueneme, California.

Date	Compensation equations (ft)
1961 to Mar. 1964	$H_{NEW} = 0.54 + 0.64 H_{OLD}$
Apr. 1964 to 1965	No compensation

NOTE:

H_{NEW} = estimate of significant height that would have been obtained by the CERC method of pen and ink record analysis (based on reanalysis of 2 months of data from Huntington Beach, California)

H_{OLD} = significant height obtained by old method of pen and ink record analysis.

Table A-56. CERC wave gage history for Pt. Mugu, California (Gage No. 3).

CERC Form 174-74 18 Mar 74		LOCATION: Three miles southeast of Port Hueneme, Pt. Mugu, California (Gage No. 3)						
COORDINATES: 34°07' N., 119°09' W.								
Type of Gage	Beginning of Proper Operation	End of Proper Operation	Explanation	Gage Length (feet)	Gage Range (ft MSL)	Water Depth (ft MSL)	Distance from seaward end of pier	Pier Length (feet)
Pressure	27 Mar. 1970		Still operative as of 1 Jan. 1975	—	-11 to +19 (mounted 29 ft below MSL)	31	1,300 feet from shore.	—

Table A-57. Number of analyzed records from Pt. Mugu, California (Gage No. 3).¹

MO YR	JAN	FEB	MAR	APR	MAY	JUN	JUL	AUG	SEP	OCT	NOV	DEC	TOT
1972		107	123	93	100	118	96	111	106	118	62	85	1119
1973	33	78	65	62	66	86	66	84	86	81	106	53	866
1974	100	99	92	71	99	96	88	79	56	74	99	84	1037

¹From 1,024-second records taken four times daily. Results from records taken before January 1973 have not been compensated for hydrodynamic attenuation due to submergence of the gage. Results taken during January 1973 to December 1974 may have been overcompensated such that significant heights are up to 20 percent too high and wave periods tend to be too short.

Figure A-88. Maxima, means, and standard deviations of significant height from Pt. Mugu, California (Gage No. 3). Computed from 1,024-second digital wave records taken four times daily. Results may have been overcompensated such that significant heights are up to 20 percent too high.

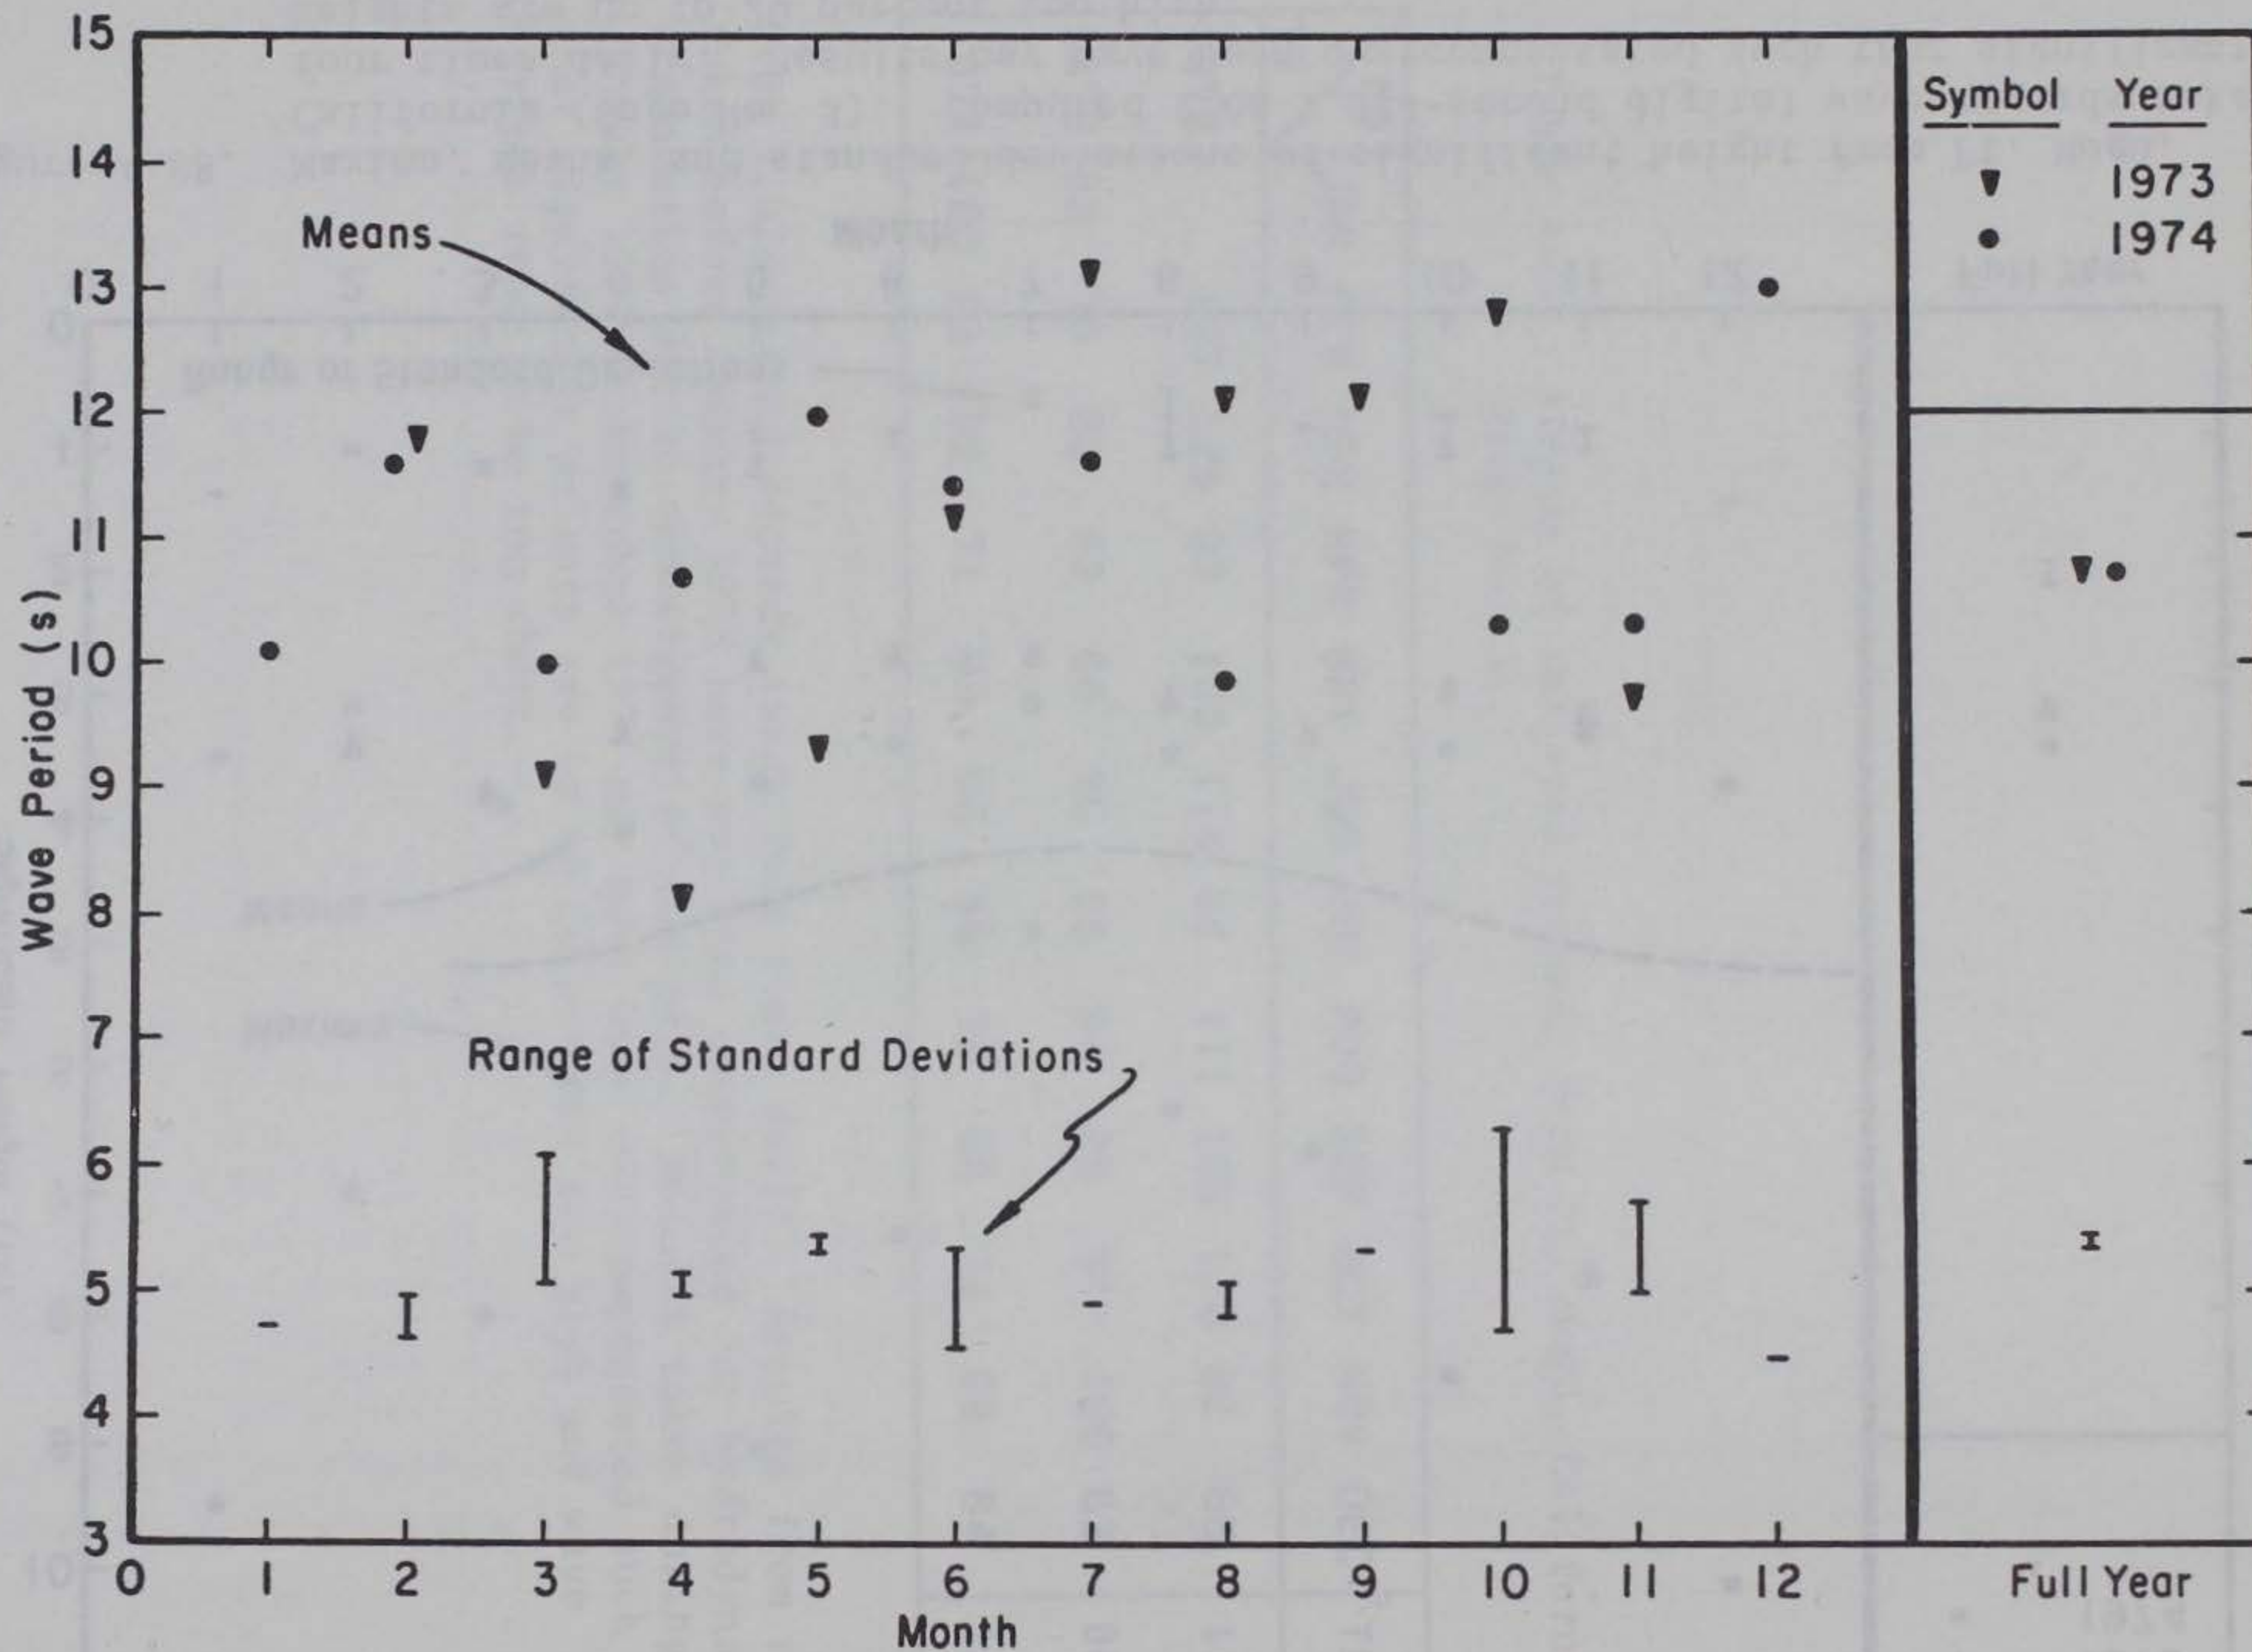

Figure A-89. Means and standard deviations of wave periods for Pt. Mugu, California (Gage No. 3). Computed from 1,024-second digital wave records taken four times daily. Results may have been overcompensated such that wave periods tend to be too short.

NOTE:

+ = computed from 1,024-second digital wave records taken four times daily; results may have been overcompensated such that significant heights are up to 20 percent high.

Figure A-90. Annual cumulative significant height distributions from Pt. Mugu, California (Gage No. 3).

Figure A-91. Annual significant period distributions from Pt. Mugu, California (Gage No. 3). Computed from 1,024-second digital wave records taken four times daily. Results may have been overcompensated such that wave periods tend to be too short; periods less than 4 seconds have been omitted.

Figure A-92. Seasonal summaries of cumulative significant height distributions from Pt. Mugu, California (Gage No. 3). Computed from 1,024-second digital wave records taken four times daily. Results may have been overcompensated such that significant heights are up to 20 percent too high.

Table A-58. Wave climate for Pt. Mugu, California.
 Distribution of significant height versus period
 (in observations per 1,000 observations).

 WAVE GAGE LOCATED AT 3 MI SE OF PORT HUENEME.

* CALMS ARE OMITTED.

NOTE: Results may have been overcompensated such that significant heights are up to 20 percent too high and wave periods tend to be too short.

Table A-60. Number of analyzed records from Pt. Mugu, California (Gage No. 4).¹

MO YR	JAN	FEB	MAR	APR	MAY	JUN	JUL	AUG	SEP	OCT	NOV	DEC	TOT
1973			37	62	92	91	67	86	86	78	107	53	759
1974	101	100	94	70	99	96	82	78	49	55	99	92	1015

¹From 1,024-second records taken four times daily. Results from records taken before January 1973 have not been compensated for hydrodynamic attenuation due to submergence of the gage. Results taken during January 1973 to December 1974 may have been overcompensated such that significant heights are up to 20 percent too high and wave periods tend to be too short.

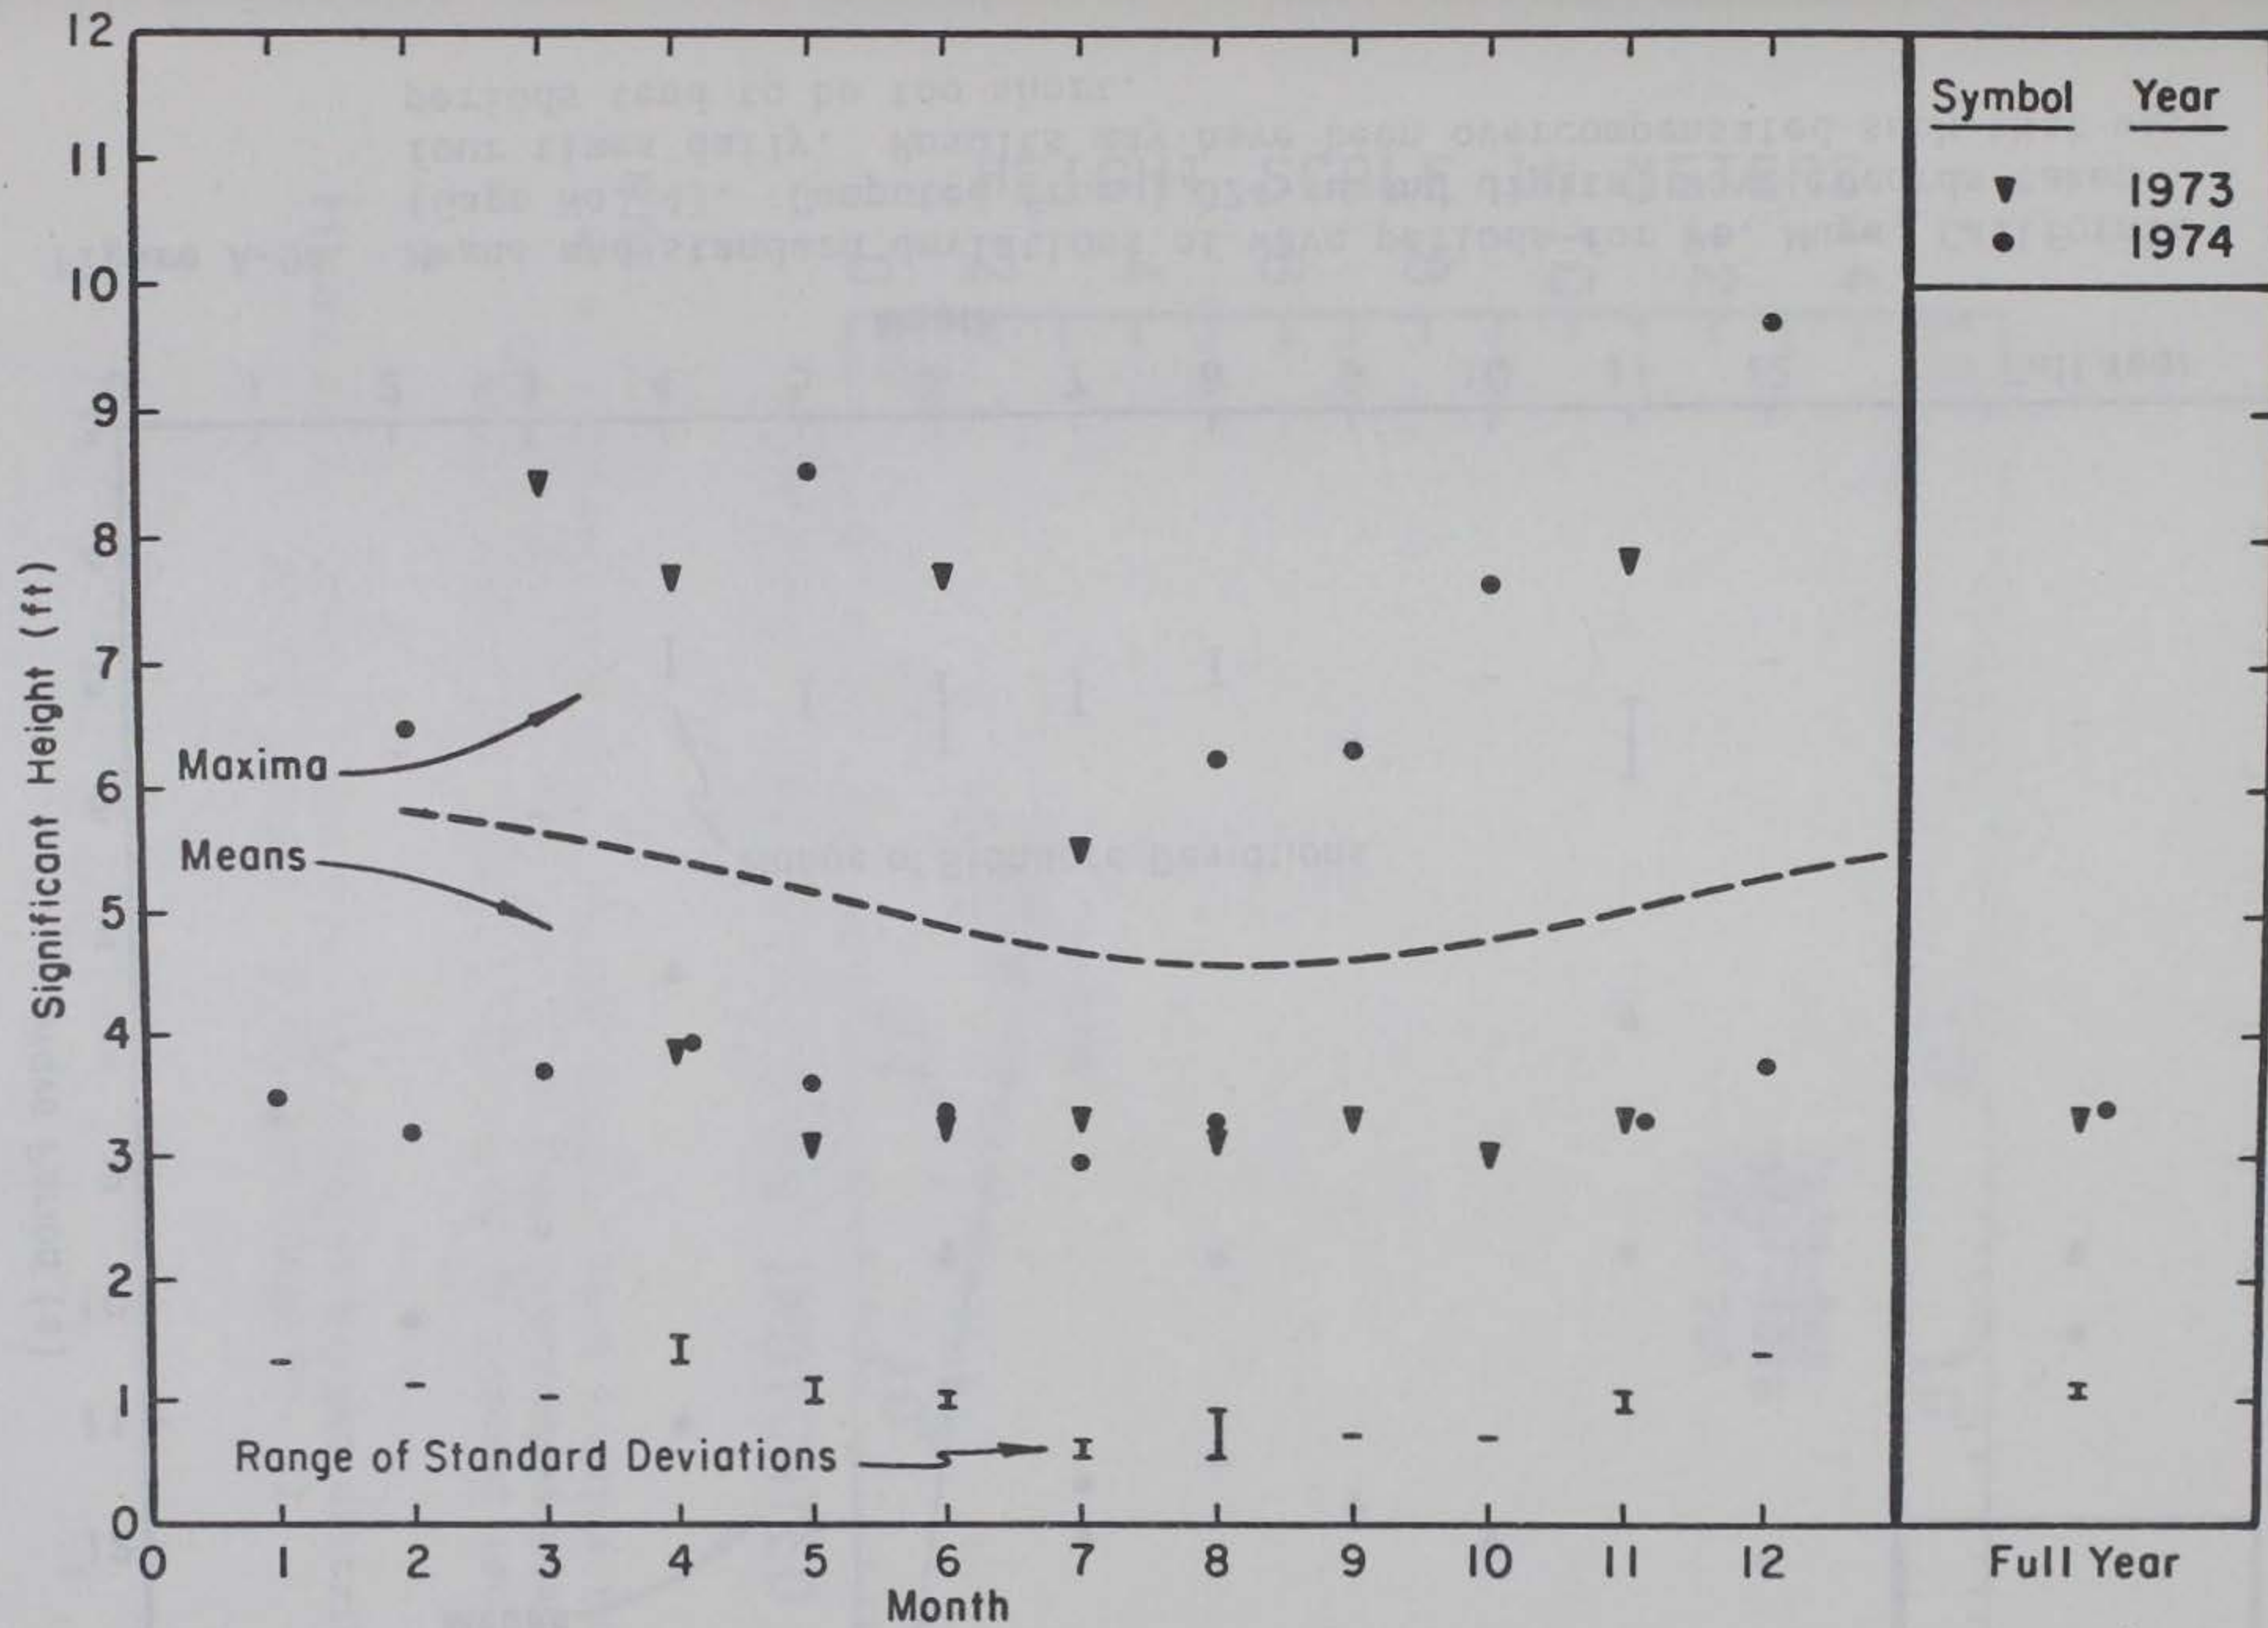

Figure A-93. Maxima, means, and standard deviations of significant height from Pt. Mugu, California (Gage No. 4). Computed from 1,024-second digital wave records taken four times daily. Results may have been overcompensated such that significant heights are up to 20 percent too high.

Figure A-94. Means and standard deviations of wave periods for Pt. Mugu, California (Gage No. 4). Computed from 1,024-second digital wave records taken four times daily. Results may have been overcompensated such that wave periods tend to be too short.

NOTE:

+ = computed from 1,024-second digital wave records taken four times daily; results may have been overcompensated such that significant heights are up to 20 percent too high.

Figure A-95. Annual cumulative significant height distributions from Pt. Mugu, California (Gage No. 4).

Figure A-96. Annual significant period distributions from Pt. Mugu, California (Gage No. 4). Computed from 1,024-second digital wave records taken four times daily. Results may have been overcompensated such that wave periods tend to be too short; periods less than 4 seconds have been omitted.

Figure A-97. Seasonal summaries of cumulative significant height distributions from Pt. Mugu, California (Gage No. 4). Computed from 1,024-second digital wave records taken four times daily. Results may have been overcompensated such that significant heights are up to 20 percent too high.

Table A-61. Wave climate for Pt. Mugu, California.
Distribution of significant height versus period
(in observations per 1,000 observations).

¹Results before 1968 obtained from 7-minute pen and ink records taken six times daily; analyzed by the first BEB method for 1948 to 1953; analyzed by the second BEB method for 1954 to February 1964; and analyzed by the CERC method for March 1964 to 1967. Results after January 1972 obtained from 1,024-second digital records taken four times daily.

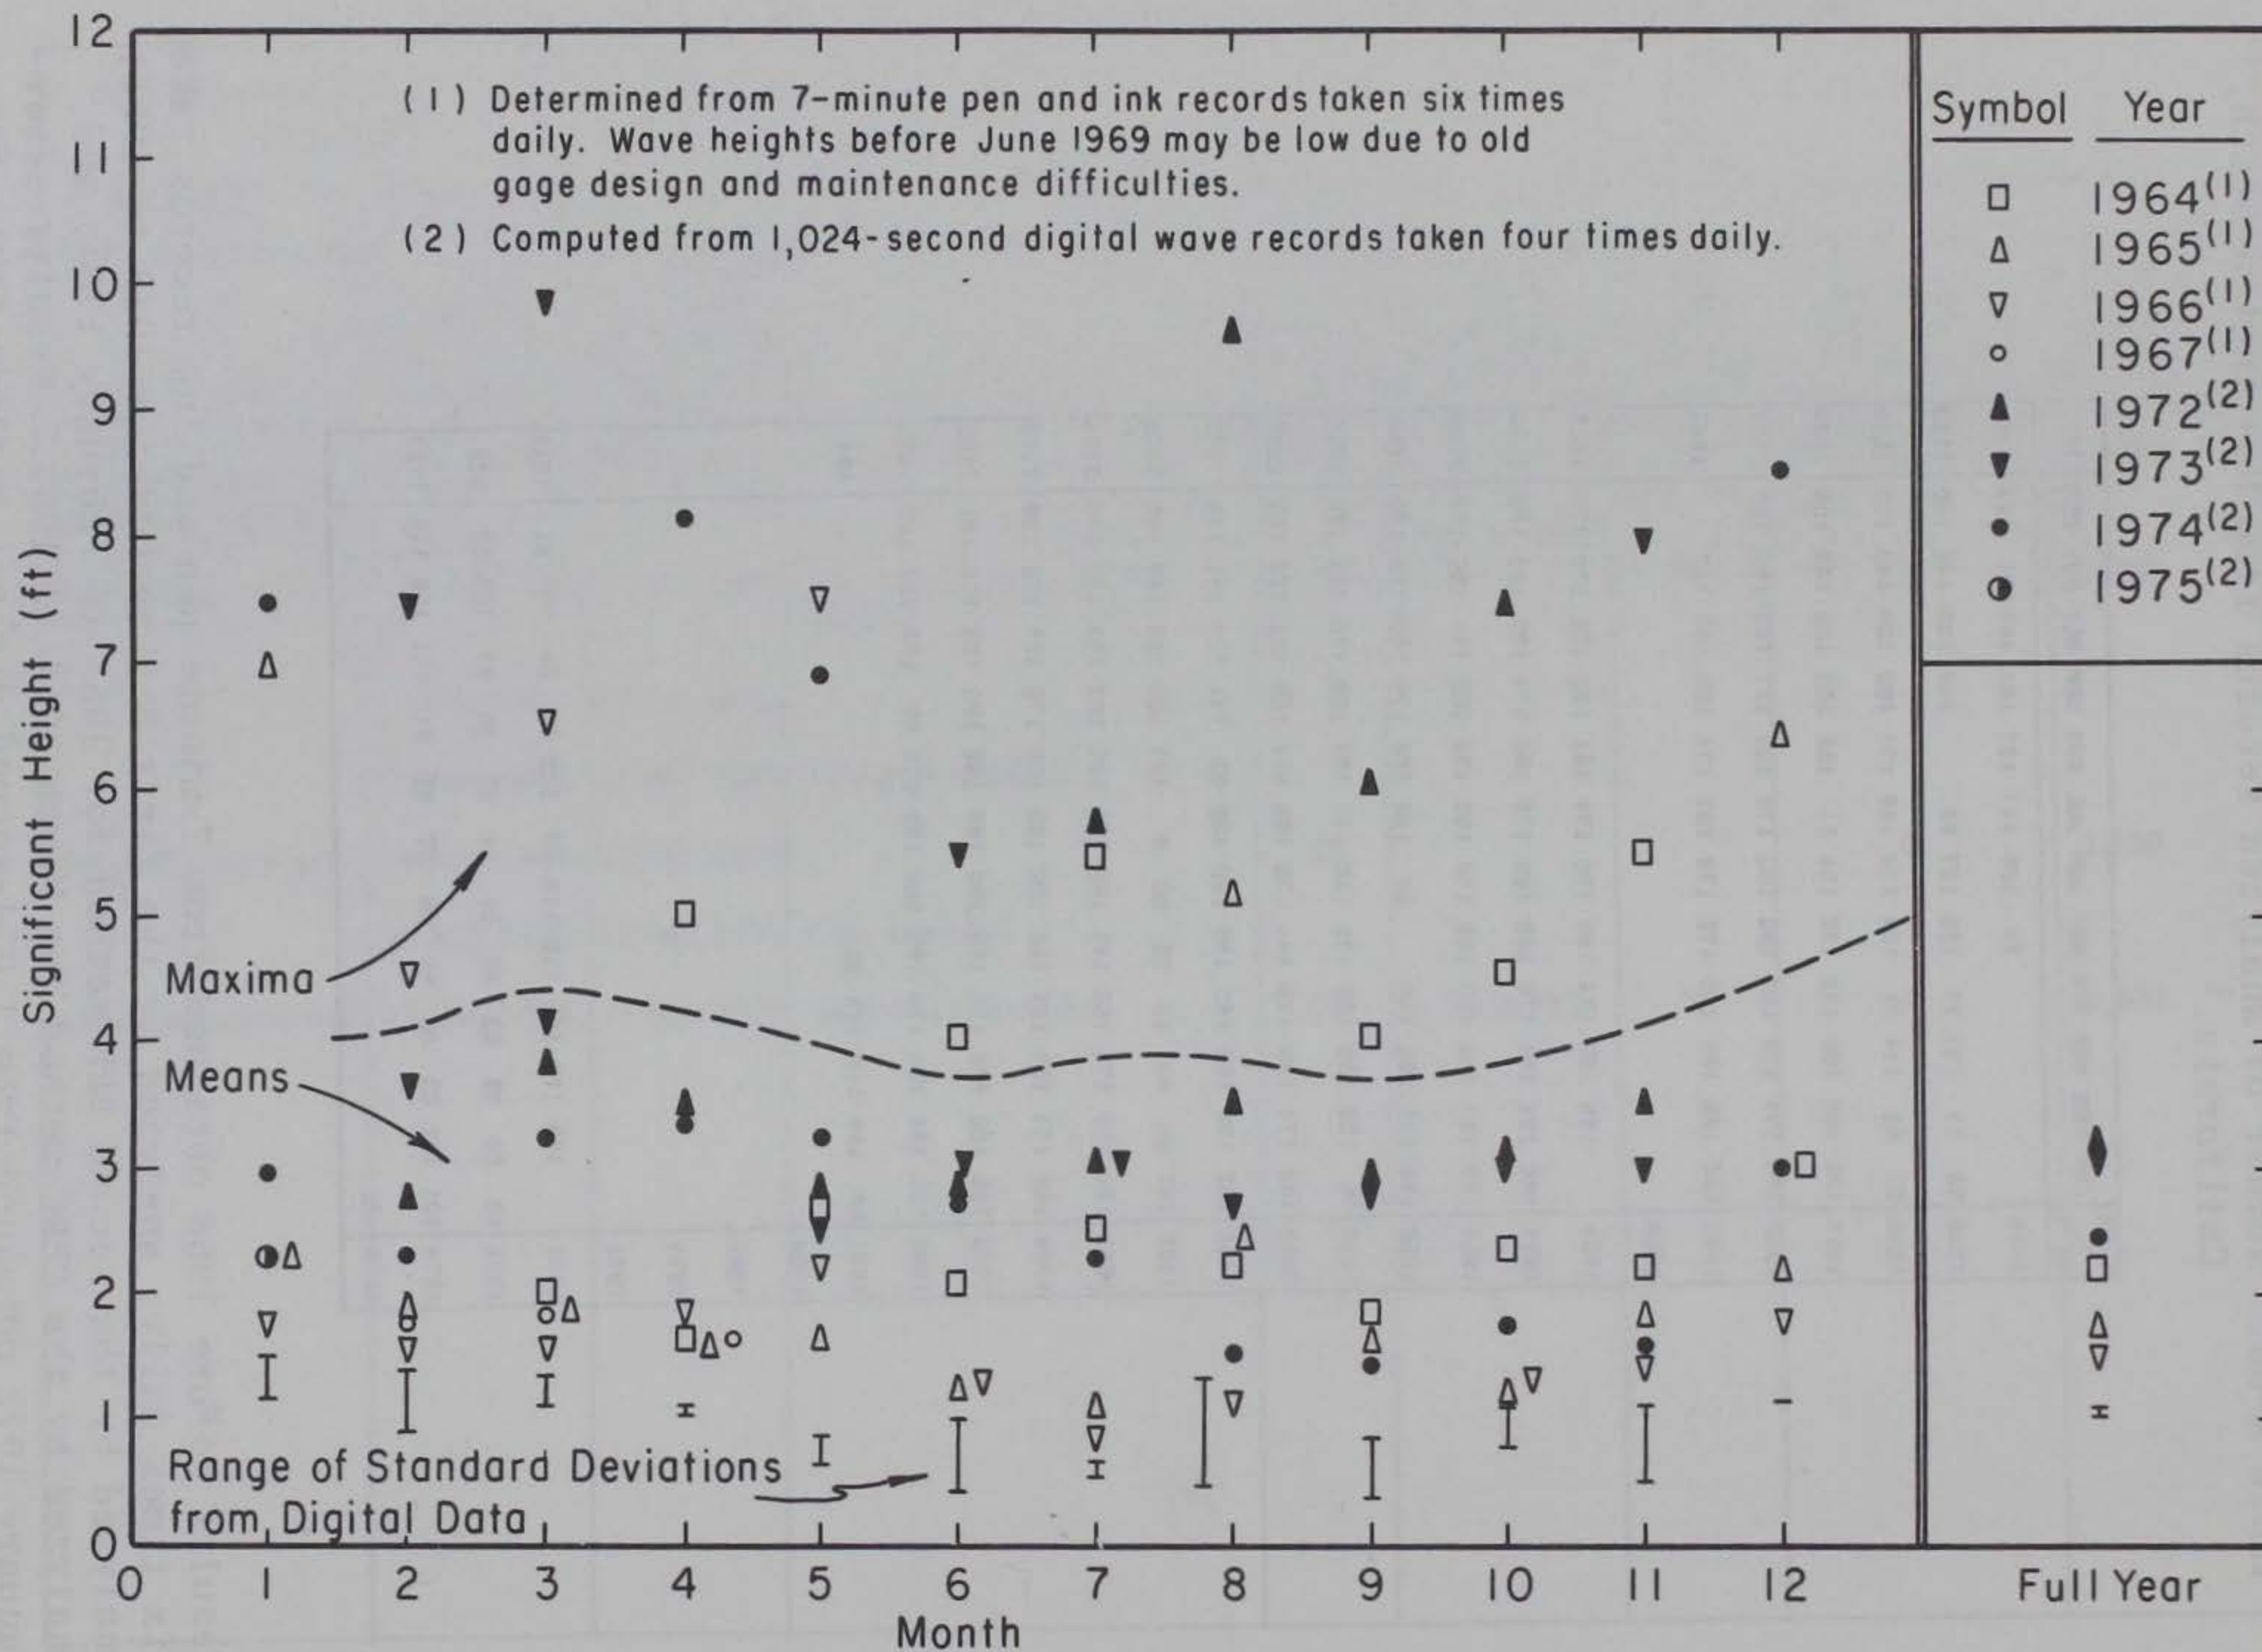

Figure A-103. Maxima, means, and standard deviations of significant height from Huntington Beach, California.

Figure A-104. Means and standard deviations of wave periods for Huntington Beach, California.

NOTE:

- + = computed from 1,024-second digital wave records taken four times daily.
- * = determined by an old analysis method from 7-minute pen and ink records taken six times daily and compensated to compare with results from recent analysis methods (see Tables A-68 and A-69); wave heights may be low due to old gage design and maintenance difficulties.

Unmarked = determined from 7-minute pen and ink records taken six times daily; wave heights may be low due to old gage design and maintenance difficulties.

Figure A-105. Annual cumulative significant height distributions from Huntington Beach, California.

Figure A-106. Annual significant period distributions from Huntington Beach, California.

Figure A-107. Seasonal summaries of cumulative significant height distributions from Huntington Beach, California. Computed from 1,024-second digital wave records taken four times daily.

Table A-67. Wave climate for Huntington Beach, California. Distribution of significant height versus period (in observations per 1,000 observations).

RESULTS OBTAINED FROM 7-MINUTE PEW AND YNK RECORDS TAKEN WITH A STEP RESISTANCE
 WAVE GAGE LOCATED AT HUNTINGTON BEACH PIER.
 * CALMS ARE OMITTED.
 Wave heights may be low due to old gage design and maintenance difficulties.

Table A-68. Comparison of results from different pen and ink wave record analysis methods, Huntington Beach, California.

Dates of data sample reanalyzed by CERC method	Significant heights ¹			Significant periods ²		
	Correlation between heights	A (ft)	B	Correlation between periods	C (s)	D
July 1950	0.93	0.02	0.89	0.69	3.00	0.70
Mar. 1951	0.77	0.25	0.82	0.56	3.78	0.61
Jan. 1958	0.81	0.09	0.65	0.50	2.12	0.75
Feb. 1960	0.89	0.07	0.81	0.54	2.34	0.81
Nov. to Dec. 1962	0.85	0.54	0.64	0.64	5.03	0.59

¹Significant height from the CERC method
 = A + B × (significant height from old method).

²Significant period from the CERC method
 = C + D × (significant period from old method).

Table A-69. Regression equations used to compensate significant height statistics for Huntington Beach, California.

Year	Compensation equations (ft)
1949 to 1950	$H_{NEW} = 0.02 + 0.89 H_{OLD}$
1951 to 1953	$H_{NEW} = 0.25 + 0.82 H_{OLD}$
1954 to 1958	$H_{NEW} = 0.09 + 0.65 H_{OLD}$
1959 to 1960	$H_{NEW} = 0.07 + 0.81 H_{OLD}$
1961 to 1963	$H_{NEW} = 0.54 + 0.64 H_{OLD}$
1964 to 1974	No compensation

NOTE:

H_{NEW} = estimate of significant height that would have been obtained by the CERC method of pen and ink record analysis.

H_{OLD} = significant height obtained by old method of pen and ink record analysis.

APPENDIX B

PROCEDURE FOR ANALYSIS OF WAVE DATA FROM 7-MINUTE PEN AND INK RECORDS
(BASED ON A RAYLEIGH DISTRIBUTION FOR WAVE HEIGHT)

1. Run the period template (Fig. B-1) along the 7-minute record until a group of fairly uniform waves is found which should contain some of the highest waves. A template can be fabricated on a clear overlay such as acetate.
2. Determine the appropriate period of the waves selected in step 1 by using the template according to instructions. When the wave period on the chart falls between two of the periods shown on the template, the analyzer may approximate what is considered to be nearest to the exact period; e.g., if the period is about the same amount longer than the 5-second period, then it is shorter than the 6-second period, the period must be about 5.5 seconds.
3. Use the table below to determine which wave should be measured in the full 7-minute record to get the approximate significant height of the waves. The wave number is determined by calling the highest wave in the full 7-minute record as wave number 1; the second highest wave is number 2, etc. Wave height is defined as the difference in elevation between a wave crest and the preceding trough.

Wave period (seconds)	Number of wave to measure
3.0	19
3.5	16
4.0	14
4.5	13
5.0	11
5.5	10
6.0	9
7.0	8
8.0	7
9.0	6
10.0	6
11.0	5
12.0	5
13.0	4
14.0	4
15.0	4
16.0	4

4. Determine the height of the wave given by step 3, in terms of small divisions on the chart paper.
5. Using the appropriate relationship between chart paper divisions and actual elevations in feet, convert the wave height determined in step 4 from chart divisions to feet. Estimate to the nearest tenth of a foot.

Use: When consecutive crests or troughs of waves as shown on a chart align with consecutive vertical lines on a template, the period of the waves, in seconds, is indicated by the number of the template
