FOREWORD

Differences in concentrations of mineral composition of beach areas along the shoreline have on occasion been used to estimate direction of movement of littoral drift and other littoral processes. Extension of these methods to the use of naturally radioactive thorium as a means of detecting direction of littoral drift has been made over a portion of the California coast from the Russian River to Point San Pedro. This report discusses these methods and the results which indicate the method to be rather quick for qualitative results and quite simple compared to normal mineralogical analysis. After separation of the heavy mineral fraction from samples taken along the beaches, radioactivity present is determined by use of a two-channel gamma-ray spectrometer with one channel adjusted on the 0.238 mev. peak from Pb^{212} in the thorium series and the other on the 0.118 mev. peak from Ra^{226} in the uranium series. As the method and its results appear of considerable interest in the field of beach erosion and shore processes, it is now being published as a Beach Erosion Board Technical Memorandum.

This report was prepared at the Wave Research Laboratory of the Institute of Engineering Research at the University of California. Much of the work was done under support by the National Science Foundation (Grant G-18123) but use was also made of data gathered concurrently by the University in pursuance of Contract DA-49-055-Eng-8 with the Beach Erosion Board for the study of beach materials and sources of beach materials along the California coast. The author of the report, Adel Kamel, was at that time a candidate for a doctoral degree at the University (in fact this report formed in part his Ph. D. thesis) and is now a research engineer and assistant professor at the Coastal Engineering Laboratory, University of Florida.

Views and conclusions stated in this report are not necessarily those of the Beach Erosion Board.

This report is published under authority of Public Law 166, 79th Congress, approved July 31, 1945.

LITTORAL STUDIES NEAR SAN FRANCISCO
USING TRACER TECHNIQUES

by

Adel M. Kamel, University of California

ABSTRACT

A method of assaying for naturally radioactive thorium as a means of detecting the direction of littoral drift of sand along a sea coast was investigated and applied to the portion of the Coast of California from the Russian River mouth to Point San Pedro. The method proved to be very quick for qualitative results and rather simple compared to mineralogical analyses.

The method involved the collection of surface and deep samples along the reach of the coast under study. The heavy minerals for a limited size fraction of the sand samples were separated by bromoform and the radioactivity present in them was counted by the use of a two channel gamma-ray spectrometer. One channel was adjusted on the 0.238 mev. peak from Pb^{212} in the thorium series and the other on the 0.118 mev. peak from Ra^{226} in the uranium series.

In this study the three factors considered in determining the direction of littoral drift along the coast were as follows:

1. The concentration of thorium (in parts per million) in the heavy minerals of a limited size fraction of the sand samples analyzed.
2. The percent of heavy minerals in the same size fraction used in (1).
3. Wave refraction diagrams.

A decrease in the concentration of thorium and heavy minerals from the source area indicated alongshore drift in the direction of decrease of both parameters, while wave refraction patterns showed a littoral sand drift in the direction of the alongshore energy component of waves breaking at an angle to the shore.

Based on the distribution of beach sand samples and their thorium and heavy minerals concentrations and wave refraction diagrams, the pattern of sand movement along the California Coast from the mouth of the Russian River to Point San Pedro was found to be from the north to the south except for a few locations where a reversal direction of littoral drift existed.

INTRODUCTION

General Problem

The source, movement, and deposition of sediments along shorelines have been studied extensively by geologists, geographers, and engineers. Johnson (1959*), defined the factors involved in the supply and loss of sand to a coast as follows:

Source of sand supply: (a) Major streams, (b) small streams and gullies, (c) cliff erosion and slides, (d) onshore movement of sand by wave action, and (e) wind action.

Sand losses: (a) Movement offshore into deep water, (b) losses into submarine canyons, (c) accretion against littoral barriers, (d) removal of sand for construction purposes, (e) wind action, and (f) abrasion by wave action.

The process by which sediments are moved along the shore is known as littoral drift and it includes beach drifting and alongshore drift (Johnson, 1919). Coarse material is moved along a foreshore in zigzag paths under the influence of swash and backwash of the waves. The process of alongshore drift is due to alongshore currents set up within the breaker zone by breaking waves approaching the shoreline at an angle (Fig. 1). Although the waves tend to become parallel to the coast as a result of refraction, they usually break at a slight angle to the shore with the result that a littoral current is induced and is effective in moving a mass of water (and the sediment placed in suspension by the breaking waves) slowly along the coast. It is this current combined with the agitating action of the breaking waves, that is the primary factor in causing movement of sand along a coastline. It is believed that the largest percentage of the littoral transport occurs shoreward of the breaking point of the waves.

Knowledge of sand sources and direction of littoral drift along a coast are of prime importance in beach erosion studies. These factors may be determined broadly by several distinct methods of approach, some of which are necessarily complementary to each other. These include:

(1) The use of standard hydrographic methods of mapping the sea bed and shoreline, aerial surveys, wave data, and refraction diagram analyses, current measurements, sampling of suspended load and bed load sediments, etc.

(2) The use of natural tracers such as heavy mineral fractions or shell inclusions in sediment samples, in relation to their source areas.

(3) The use of radioisotopes as tracers for labeling sediment samples, either by incorporation of the activated material in artificial sediment, or by chemical or physical adhesion as a radioactive film on the particles of the real sediment, or by embedment within the particles (in the case of pebbles).

*See references p. 40

HYD-8304

Waves breaking at an angle with beach generate longshore currents; north of Oceanside, California.

Fig. 1

(4) The use of luminophors as tracers for labeling sediment samples, either by incorporation of the fluorescent material in artificial sediment or shingle, or by adhesion as a luminescent film on particles of natural sediment.

(5) The use of hydraulic models with movable beds of artificial materials to simulate prototype sediment processes.

Along the California Coast, a method of using radioactive tracers presented itself in that there are several locations on the coast where radioactive material is added naturally to the beaches. This material is thorium (Th^{232} , 0.238 mev.). It is added at discrete places along the coast where rivers flowing through thorium-rich granite outcrops reach the coast or where the thorium-rich granite itself outcrops at the seacoast. This thorium was used as a means of detecting the direction of littoral drift of sand along the portion of the California Coast from the Russian River mouth to Point San Pedro.

Summary of Past Studies on Littoral Drift

Formulas for rate of littoral drift:

Many attempts have been made to determine the amount of material migrating along a shoreline. The principal factors affecting the rate of littoral transport have been studied in the laboratory (Krumbein, 1944; Saville, 1950; Johnson, 1952; Sauvage De Saint Marc; 1955). However, complete understanding of the problem is still lacking, although such information is of utmost importance in the design and development of navigation channels, ports, and beaches. Advance towards a better understanding of this problem has been made in recent years, but the effect of waves and currents on littoral drift still defies accurate prediction of certain phenomenon. Existing formulas for estimating the amount of littoral drift all are of a semi-theoretical or entirely empirical nature inasmuch as some of the physical elements are not completely understood. Some of the more common formulas are:

1 - The Los Angeles formula (1937):

$$Q = 1/2 K_1 W_e \sin 2 \alpha$$

2 - Eaton (1951) gave the formula (identical to formula 1 above):

$$Q = K w_e \sin \alpha_b \cos \alpha_b$$

3 - Caldwell (1956) gave the formula:

$$Q = 210 E^{0.8} \quad \text{where: } E = E_t \sin \varphi \cos \varphi$$

4 - Bajorunas (1961) gave the formula:

$$Q = a E_o^n \sin \alpha_o \left[1 - e^{-bD \cot \alpha_o} \right]$$

Where:

Q = littoral drift factor

W = Total work accomplished by all waves of given period
and direction

e = wave energy coefficient

α, ϕ = angle between the wave and the breaker line and the shore

E = the alongshore energy

E_o = deep water wave energy

k, n, a, b = constants

D = length of reach

subscript b = breaker

subscript o = deepwater

Other formulas are those by Iwagaki and Sawargi (1960), and Ishihara and Sawargi (1960).

The above authors agree that there is a relationship between the rate of littoral drift and the energy component parallel to the shore, although energy is not a vector and a thorough discussion of these matters must necessarily involve the stress exerted on the bottom by the waves and the alongshore currents. The oscillating water motion in a wave places sediment into suspension and the littoral current furnishes a unidirectional movement. Such motion meets the practical difficulty that it has not been possible to develop reliable theories for material transport in rivers and channels with unidirectional flow, although considerable advances have been made by Einstein (1950). As long as we are not able to solve this material transport problem, it is unlikely that the much more complex problem involving oscillating water motion will be solved in the near future.

Rates of littoral drift by measuring deposition or erosion:

Another and more direct approach to the problem is the estimation of probable rates of transport along natural shorelines from the amount of material trapped by shore structures, either natural or man-made, and from a knowledge of sources of supply. Studies of this nature are those by Johnson, 1952; 1957; 1959). Johnson (1952) has studied the problem of accretion in the Santa Barbara harbor since the construction of the breakwater in 1929. In 1957 he gave a summary of measured rates of littoral drift along coasts of the United States and presented the method of rate

determination (whether by scour or accretion), and in 1959 he summarized the various sources of supply and loss of sand to the coast and applied them to a reach of the coast of California. Quantitative estimates of the annual amounts of sand supplied or lost were presented.

Similar studies are those by Grant and Shepard (1936, 1937, 1939, 1946; Shepard, 1951; Handin, 1951; Pincus, 1954; Chieruzzi, 1958).

Natural tracers:

Mineral analyses of samples drawn from representative sites in a study area are helpful in the determination of the direction of littoral drift. The samples are subjected to sieve analyses and the heavy minerals from the fractions are processed microscopically by X-ray, differential thermal analyses or by magnetic separator, and classified according to their geological type. Their roundness, sphericity, color and corrosion properties also are recorded. The fluvial sources of some of these minerals can be traced and their distribution along the coast may sometimes yield important qualitative information in regard to the trends of sediment transport.

Rittenhouse (1944) determined the relative importance of various sources of sediment, which was largely sand, from the heavy mineral composition of channel deposits of the Rio Grande and its tributaries. In this study, the hydraulic ratio basis of comparing mineral composition was used. This method appears to satisfy the three objections to methods in common use in rivers, namely: it uses both the frequency and absolute amounts of heavy minerals, it eliminates apparent differences in mineral composition that are associated with differences in texture of the bed deposits, and it effectively transposes the data from bed samples into usable data on mineral composition in the stream load.

Trask (1952) determined the source of sand deposited in Santa Barbara harbor by mineral grain studies. Mineralogical studies of this type generally are inconclusive, because the minerals in beach sand are so thoroughly mixed that distinctive differences do not wholly exist. However, if part of the sand is derived from an area in which the rocks differ in mineral composition from the rocks in places from which the remainder of the sand is derived, the source of the sand is indicated by the rate of change in mineral content with respect to distance along the coast, as the original sand is progressively diluted with sand from other areas. Two studies of the mineral composition of the sand at Santa Barbara were made: (1) in the harbor itself in order to ascertain if the mineral content varied significantly in and near the harbor and associated beaches; and (2) along the coast west and north of the harbor for a distance of more than 250 miles, in order to investigate migration of sand along the coast. The first study in the immediate area of Santa Barbara showed no distinctive difference in mineral content; consequently this study contributed little information of aid in understanding sand movement between the harbor and

the beaches to the east. The second study of sand along the coast west of Santa Barbara has shown very clearly that a significant proportion of the sand at Santa Barbara comes from a distance of more than 100 miles up the coast. This conclusion was based upon the fact that the mineral, augite, a black ferromagnesian silicate found commonly in basic igneous rocks, is present in appreciable but constantly diminishing amounts from its source near Morro Bay southward for more than 100 miles to Santa Barbara. By a similar analysis Trask (1955) showed that sand moves around Southern California promontories.

McMaster (1960) made a study on sand movement along the Rhode Island coast. In this area beach sands are composed of a great variety of minerals, the most common of which are amphiboles, chlorite, garnet, staurolite, and black opaques in the heavy fractions and feldspars and quartz in the light fractions. Counts of those fractions from samples collected at one-mile intervals were used as basic data for multivariate and trend analyses. The character of source materials and pattern of beach drift are believed responsible for areal differences in mineral composition. The decrease in heavy mineral percentages eastward with a general uniformity of grain size as well as over-all decrease in abundance of amphiboles and feldspars and increase in garnet and black opaques seem to reflect an eastward drift away from the source area.

Artificial tracers:

1. Use of radioactive isotopes

Methods of sampling and mineral analyses are somewhat cumbersome in that they require a considerable amount of field work and laboratory research. Furthermore, bed sampling is often impossible under rough sea conditions and in the surf zone. These limitations may be avoided by the use of radioisotopes for labeling specimens of sediment, since these can be used in any sea state and are quite expeditiously traced with suitable detectors. A considerable literature has developed over the last five years on the detection of the movement of sediment by radioactive tracers. Many experiments have been conducted to study the feasibility of using new techniques for determining the general direction in which littoral material moves (Hours, 1955; Inose, 1955; Putman, 1956; Steers, 1957; Krone, 1957, 1959, 1960; Forest, 1957; Smith, 1957; Arlman, 1957; Reid, 1958; Germain, 1958; Davidsson, 1958; Gibert, 1958; Inman, 1959; Svasek, 1961; and Ijima, 1960). A brief review of these techniques is as follows:

Tracers. Glass, ground to the particle size distribution of the sediment under study and labeled by incorporated radioactive isotope, has been the most commonly used sediment tracer (Putman, 1956; Reid, 1958; Germain, 1958; Forest, 1957; Inose, 1955; and Hours, 1955). The method of preparation preferred by most investigators is to incorporate an inactive isotope of the label in the glass, grind it to the desired size distribution, and activate the label by neutron irradiation just prior to placing the tracer

in the field. Boron-free soda glass is widely used. Ground glass has been used extensively for tracing sand movements. It also has been used for studying the movement of silts (Putman, 1956) and muds (Hiranandani, 1960). Natural sediment materials have been labeled with sorbed isotopes by investigators concerned with a closer simulation of sand and gravel particles (Smith, 1957), and by investigators seeking a method for labeling large quantities of sand (Gibert, 1958; Arlman, 1957). Tracers for pebbles have been made both by drilling natural or artificial pebbles and inserting an active label into them (Forest, 1957; Inose, 1955; and Steers, 1956), and by sorption (Smith, 1957).

Labels. A number of radioactive labels have been investigated and used in tracing sediment movement. Most such labels (Sc - 46, Zn - 65, Cr - 51, La - 140, Ta - 182, A - 110, Au - 198, Ir - 192) emit gamma radiation which can be detected in place. For detection most of the investigators have used bundles of Geiger-Muller detectors; however, two investigators used scintillation detectors (Hours, 1955; Putman, 1956). None of the investigators used discriminators with scintillators to reject background activity. Most studies of sediment movement by tracer techniques involved sand (Putman, 1956; Reid, 1958; Germain, 1958; Forest, 1957; Inose, 1955; Hours, 1955; Gibert, 1958); two used pebbles (Forest, 1957; Steers, 1956); one used silt (Putman, 1956); and one used mud (Hiranandani, 1960). In all applications reported above measurements were made of the redistribution by wave action or tidal currents of material placed on the sea bottom.

2. Use of luminophors:

Luminophors have been used in many instances as a means for the detection of sediment movement (Zenkovich, 1958; Vendrov, 1957; Russell, 1961; Halcrow, 1961). In this method natural sand particles are coated with a colloidal film of finely dispersed luminescent material which appears fluorescent when viewed in the darkness under ultra-violet light. The procedure by which tracer sediment has been prepared in England (Russell, 1961), consists of mixing the sediment samples with fluorescent dye and plastic glue and then crushing and sieving the material to the desired granular distribution.

Tracer pebbles have been prepared artificially from crushed concrete in which granulated fluorescent dye in plastic glue has been incorporated as a fine aggregate. Dyes used are Rhodamine B (red); Primuline (green); Uvitex (blue); and Araldite. The variation of colors opens up possibilities of discriminating between sediment movement at various depths or at one depth as a function of grain size. Also, influences of different densities or of geometric nonsimilarities in particle shape can be studied effectively. Color differences have already been used to good advantage in tracing the velocity of progression of sand bars and in detecting the speed of advance of different fractions of sediment. Different colors of luminophors also are valuable for distinguishing test materials used at different times in the same locality, or at the same time in adjacent areas where there are

likely to be overlapping effects. As compared with radioisotopes, luminescent tracers offer advantages of being less costly, capable of more abundant and easier production and of being safe to handle.

PRINCIPLES OF NATURAL RADIOACTIVITY

Natural Radioactivity

All elements found in nature with atomic numbers greater than 83 (bismuth) are radioactive. In addition, a few of the lighter elements, namely, potassium, rubidium, samarium, lanthanum, rhenium, and perhaps one or two others, possess feeble radioactive properties in normal states (Glasstone, 1958). A substance or element, is radioactive when the atoms of which it is composed disintegrate spontaneously regardless of whether or not the emission of radiation can be readily detected in the process. A radio-atom in decaying may emit one or more gamma rays or it may emit none. But, no matter how many gamma-rays are emitted, such gamma photons will have a characteristic wave length or energy. Abundance of gamma rays of different energy resulting from the breakdown of the two major natural radioactive decay series, i. e. uranium and thorium, is indicated by the partial list in Table 1. Only prominent ones emerge as peaks above the base spectrum.

Radioactive Equilibrium

An atom that disintegrates to form another atom is called the parent, and the product is called the daughter. A radio-atom is in a state of secular equilibrium with its disintegration product when the same number of atoms of the daughter nuclide disintegrate as are formed in a unit of time. Thus, in a radioactive decay series in equilibrium, the number of atoms of the nuclide being formed is exactly equal to the number of atoms of that nuclide disintegrating. The number of disintegrations per unit time, therefore, is the same for each member in the decay series. As all members of the decay series do not decay at the same rate, a greater amount of the long-life nuclides will have to be present to provide the same number of disintegrations per unit time as those coming from the short-life nuclides; consequently, the amount of nuclide present in a decay series in equilibrium is directly proportional to its half-life,

$$\lambda_1 N_1 = \lambda_2 N_2 = \lambda_3 N_3 = \dots = \text{constant}$$

where N is the number of atoms of the daughter present and λ is its decay constant. A state of non-equilibrium exists when all or part of one or more of the daughters or parents is physically removed from the decay series. If a nuclide with a short half-life is removed, equilibrium can be rapidly regained. If a nuclide with a long half-life is removed, it may be millions of years before complete equilibrium is regained between all members of the decay chain.

* From Hollander, Perlman, and Seaborg (1953).

Source of Radioactivity

For a natural rock practically all the gamma radiation comes from three sources, namely, K^{40} , U^{238} series, and Th^{232} series (Adams et al, 1958). Figures 2, 3 and 4 show gamma scintillation spectra for potassium, uranium, and thorium, respectively. Uranium is generally found with thorium in nature in a ratio of about 10 parts of thorium to one part of uranium. The gamma rays from U^{238} and Th^{232} themselves are of such a low energy value as to make direct measurements impractical. Where secular radioactive equilibrium prevails, the abundance of U^{238} or Th^{232} can be determined by measuring the activity of any daughter in the respective series. This follows from the constant ratios that exist between the concentrations of the various members of a series in an equilibrated sample.

Techniques of this type, capable of measuring a few parts per million of thorium and uranium present in common rocks, have been developed by Hurley (1956) and by Adams, et al (1958). The main difference between the two gamma-ray techniques involves the choice of spectral energies. Hurley used three channels centered at the following energies: 0.18 and 0.238 Mev. for uranium and thorium, and 1.46 Mev. for potassium. With this choice of energies the potassium interference at 0.18 and 0.238 Mev. could be neglected only for samples containing more than 100 ppm. of equivalent uranium in equilibrium with its daughters. For Adams' work higher energy gamma rays were chosen: 1.86 Mev. from Bi^{214} in the uranium series and 2.63 for Tl^{208} in the thorium series. With these energies potassium can be ignored even when present in higher concentrations, because its spectrum contributes no appreciable gamma ray pulse above 1.6 Mev. Thus it is possible to determine the abundance of uranium from only two spectral measurements. Although this scheme has the advantage of less interference from higher energy gamma rays, it has the disadvantage of a lower counting rate. In the present work, the sand samples analyzed had very low activity; consequently the energy levels used by Adams were undesirable.

In California rocks potassium is found in the following forms (Pabst, 1938): Arcanite, Hanksite, Potash Alum, Vollaite, Krausite, Metavoltine, Alunite, Jarosite, Arthoclase, Microcline, Phillipsite, Celandorite, Apophyllite, Muscovite, Roscelite, Biotite, Phlogopite, Lepidolite, Glauconite, and Neptunite. Of these the following have a specific gravity higher than bromoform (2.87 at 20°C); Jarosite (3.15-3.26), Neptunite (3.19-3.23); Biotite (2.67-3.16), and Muscovite (2.76-3.0). Knowing that uranium is found in the form of Monazite (9.15), which is strongly radioactive, and that thorium is in the form of Thorite (5.2-5.4), it is obvious that the Monazite and Thorite particles will settle much faster than

FIG. 2 GAMMA-RAY SPECTRUM FOR K_2CO_3 FIG. 3 GAMMA-RAY SPECTRUM FOR UO

FIG. 4 GAMMA-RAY SPECTRUM OF ThO

Potassium in any of its forms. Consequently, if we do not wait until the Potassium particles settle down,* the heavy minerals separated will not contain potassium.

In the present work bromoform (2.87 at 20°C) was used for the following reasons to separate the heavy minerals including thorite, monazite, and zircon from the sand samples:

1. Decrease source absorption effect.
2. Elimination of the potassium minerals present in the sand samples since most of the potassium minerals have a specific gravity less than that of Bromoform (2.87 at 20°C). The gamma spectrum of the potassium free heavy minerals will not have a 1.46 Mev. peak from K^{40} in the potassium series which interferes with the 0.188 Mev. and 0.238 Mev. peaks in the U^{238} and Th^{232} series respectively. This elimination of the 1.46 Mev. K^{40} peak will enable us to use the 0.188 and 0.238 Mev. energy levels for counting the abundance of U^{238} and Th^{232} respectively present in the heavy minerals. These energy levels, i.e. 0.188 and 0.238 Mev. have the advantage of giving a high counting rate which is necessary in the analysis of samples of such low activity.

Figure 5a shows the spectra of a sand sample before separating its heavy minerals with bromoform, and Figure 5b shows the spectra of the heavy minerals of a sand sample separated by bromoform. (Notice the disappearance of the 1.46 Mev. peak from K^{40} in the potassium.)

3. The concentration of thorium (in parts per million) in a limited size fraction of the heavy minerals of the sand samples and the concentration of heavy minerals (in percent) in the same size fraction of the sand samples are to be used as parameters for determining the direction of littoral sand drift along the coast as explained in the next chapter.

*Exact calculation of the time required for each particle to settle by using Stokes' equation or Rubey's impact equation is impossible since the assumptions used in both equations are not completely satisfied in this case. A rough estimate of the settling time was made which gave the following ratios between the settling time of Monazite, Thorite, and Potassium -1:2.5:16. However, we cannot depend on these ratios and the use of another liquid of higher sp. gr. than 3.26 (Methylene Iodide, 3.32 at 20°C) is recommended if potassium is known to be present in the sand samples.

INVESTIGATIONAL PROCEDURES

General Approach

It is well known that beach sands are among the best sorted of natural sediments. They are subject to a progressive sorting when transported by alongshore currents and to a very effective local sorting by the oscillatory motion of the waves. The contention that sediment transported by alongshore currents travels chiefly in suspension is supported by the textural characteristics of the beach sands. Silt and clay are absent; very fine sand is rare. Any effects of progressive sorting along the shore must, therefore, be explained on the basis of transportation in suspension. These effects may be due to sorting according to grain shape, size, and specific gravity. Progressive sorting according to size, shape, and specific gravity may be due to a progressive decrease in the competency of the transporting agent or to fluctuations in the competency with a lagging behind of the larger, spherical, and heavier particles which move only occasionally during periods of maximum competency. The competency of the alongshore current would seem to depend on the ability of the waves to put sediment of a certain grain size in suspension, and then on the ability of the current to move the suspended load. In the present study the choice of the concentrations of both thorium and heavy minerals in parts per million and percent, respectively, in sand samples collected at mid-tide from different places along the beach, are believed to be two good parameters for the study of the effect of progressive sorting and consequently the determination of the direction of littoral drift along the coast.

A decrease from a source area in the concentration of thorium in ppm. and/or the concentration of the heavy minerals in percent should indicate alongshore drift in the direction of decreases of both parameters.

Local sorting on the other hand, need not be a result of transport in suspension, and its effects must not be confused with those of progressive sorting. To eliminate the effect of local sorting on the sand samples, comparisons between the concentrations of thorium and heavy minerals present in these samples should be made only for a very limited size fraction and not for the whole sample, e.g., a size fraction from 74 to 177 microns.

Since thorite is generally found in the size fraction finer than 125 microns (Hutton, 1951), and since the concentration of heavy minerals is also higher in the fine fraction, it was found that the best size fraction suited for this study is that from 74 to 177 microns. For samples where there is not enough fine materials, comparison was made for the size fraction from 125 to 250 microns.

Method of taking sand samples

A series of samples of beach and river sands were collected along the California Coast between north of the Russian River and Point San Pedro, a

distance of more than 90 miles. The surface sand samples were taken by scraping the surface with a straight edge, drawn parallel to the shore and penetrating only a few millimeters in depth. Such a sample can be of the required volume, yet come from a grain-size population which is similar in all its areal parts, representing a unique hydraulic condition of deposition. Since littoral sand transport may change direction with time, and since the desired object is to define the direction of sand movement, it is clear that sand samples must be collected which represent only one general direction, that is, all samples for comparison must be of sand moving during one short time interval. For this reason all samples were taken at mid-tide within a period of three days.

Some deep samples also were collected at the same time and from the same location as the surface samples. These deep samples were taken at a depth of one foot by digging a hole of about one square foot area and one foot deep.

Instrumentation

The spectra of uranium and thorium series (Figure 6) show that the peak caused by lead 212 in the thorium series occurred in a region of fairly constant response in the uranium series and might best fulfill the needs for discrimination of the two series. Furthermore, higher counting rates at this low-energy part of the spectrum make it desirable to work in this part of the spectrum. In a radioassay with gamma rays of this low energy level, the thickness of the source must be small so that the photo-peaks are not swamped by compton-scattered radiation from within the source, otherwise a correction should be made as discussed in Appendix III.

Background determination

The analysis of the radioactivity of the sand samples was done in a room that is not radioactively contaminated. The background counting in this room was very constant which is the required case for effective radiometric work when the assayed samples are weakly radioactive. Since the gamma rays concerned are from natural sources of low activity, it is necessary:

1. To maximize the total count-to-background ratio, for this reason a counting time of three hours on the average was used.
2. To minimize instrumental drifts - which are critical in attempts to stay close to the top of the peak. This difficulty was overcome by running standards at frequent intervals.

The average background during the analysis was found to be equal to 4.308 cpm. at 0.188 Mev. and 4.888 cpm at 0.238 Mev. For a counting period

FIG. 6 COUNTING CHANNELS FOR THORIUM AND URANIUM

of 200 minutes on the average, the minimum detectable counting rate (M.D.C.) = $2 \sqrt{\frac{2nb}{2}}$, where nb is the background count in cpm. For the present study

M.D.C. at 0.188 Mev. = 0.417 cpm.

M.D.C. at 0.238 Mev. = 0.444 cpm.

Method of analysis and tests

The samples were washed with fresh water to remove sea-salt, dried, and then analyzed mechanically with sieves by the customary procedure of using a rotary shaker and a period of shaking of 30 minutes. The size fraction 74 to 177 microns (for some samples size fraction 125 to 250 was also separated) was placed in bromoform, (specific gravity 2.87 at 20°C) for the separation of the heavy minerals (Krumbein and Pettijohn, 1938). The heavy minerals so separated were weighed and placed in a plastic container which was then placed in the top of the detector for counting.

The radiation from the radioactive minerals present in the sample was determined by counting at two bands centered at 0.238 Mev. and 0.188 Mev. for thorium and uranium, respectively, for a period of about three hours. Each analysis included one or more calibration with a standard. The drift error depends on the time interval between the calibrations. The counting error is the square root of the total count.

The operating procedure was as follows: A standard thorium source (4100 C.P.M.) was used to correct for variations in the counting response. After several measurements of this standard, a mean value for each channel was found, and some arbitrary value close to the mean value was chosen to represent a datum for the channel. Henceforth, all readings were corrected with reference to this datum. Thus, if the standard source was run before and after an unknown and showed that channel 2 is counting 5 percent below the datum level, the reading for the unknown was corrected upward by 5 percent to make it homogeneous with the fixed calibration constants, which were also based on the datum values.

At the start of a batch of samples the two channels were centered on the valley and the peak, respectively, by using a thorium-rich source and varying the base-line discriminator a small amount each way. A standard uranium source was then run, preceded and followed by the standard thorium source, which was always used to correct the measured values for instrument drift (See Appendix II for adjusting the gamma-ray spectrometer). After this, the unknowns were run alternately with the thorium standard.

The calculation of the quantities of thorium and uranium in an unknown was as follows: "Counting rate" means net counting rate after background

has been removed and corrected for drift by calibration with the thorium standard.

T = weight of thorium in thorium standard in micrograms.

T_1 = counting rate from thorium standard in channel 1 in counts per minute.

T_2 = counting rate from thorium standard in channel 2 in counts per minute.

U = weight of uranium in uranium standard in micrograms.

U_1 = counting rate from uranium standard in channel 1 in counts per minute.

U_2 = counting rate from uranium standard in channel 2 in counts per minute.

R_1 = counting rate from unknown sample in channel 1 in counts per minute.

R_2 = counting rate from unknown sample in channel 2 in counts per minute.

In the value found for R_2 if X , Y are the counts per minute due to uranium and thorium, respectively, the solution of the following equations will give the required results:

$$(U_1/U_2) X + (T_1/T_2) Y = R_1 \quad (1)$$

$$X + Y = R_2 \quad (2)$$

$$\frac{X}{\begin{vmatrix} 1 & -R_2 \\ (T_1/T_2) & -R_1 \end{vmatrix}} = \frac{Y}{\begin{vmatrix} -R_2 & 1 \\ -R_1 & (U_1/U_2) \end{vmatrix}} = \frac{1}{\begin{vmatrix} 1 & 1 \\ (U_1/U_2) & (T_1/T_2) \end{vmatrix}}$$

$$X = \frac{R_1 - (T_1/T_2) R_2}{(U_1/U_2) - (T_1/T_2)} \quad \text{counts per minute}$$

$$Y = \frac{-R_1 + (U_1/U_2) R_2}{(U_1/U_2) - (T_1/T_2)} \quad \text{counts per minute}$$

$$\text{Experimentally } (T_1/T_2) = 0.386$$

$$(U_1/U_2) = 2.832$$

$$(U_1/U_2) - (T_1/T_2) = 2.446$$

When 10 or more grams of heavy minerals were assayed, correction for sample size was made as indicated in Appendix III.

ANALYSIS OF RESULTS

Samples were obtained at a number of localities to investigate the following problems:

- A. To study the direction of littoral drift along a reach of the California Coast.
 - 1. Sample Nos. 1 to 59 (Table 1, App. IV) were surface and deep samples collected at mid-tide during the period between June 15 and June 18, 1961. (Fig. 7)
 - 2. Sample Nos. 60 to 69 (Table 2, App. IV) were bottom samples collected from the Pacific Ocean in the vicinity of the San Francisco Bar. (Fig. 11)
- B. To study the variation in thorium concentration along a beach profile.
 - 1. Samples from a to h (Table 3, App. IV) were surface samples taken along a profile at location 30 at Drakes Bay on June 6, 1961. (Fig. 13)
- C. To study the variation in thorium concentration with time at a specific location on a beach.
 - 1. Samples from a to d (Table 4, App. IV) were surface and deep samples taken at mid-tide at location No. 48 at different times. (Fig. 14)

In this study the three factors considered in determining the direction of littoral drift along the part of the California Coast from the Russian River to Point San Pedro are as follows:

- 1. The concentration of thorium (in parts per million) in the heavy minerals of a limited size fraction of the sand sample analyzed.
- 2. The percent of heavy minerals in the same size fraction used in (1).
- 3. Wave refraction diagrams.

The first factor, i. e., concentration of thorium in ppm., will represent the effect of progressive sorting caused by the littoral current on the beach sands. This will result in a dilution of the amount of thorium present in the sample in the direction of littoral drift. This will be noticed as a decrease in the concentration of thorium with distance from the source area, in the direction of littoral drift. The second factor, i. e., the concentration of heavy minerals in percent, will also represent the

effect of progressive sorting by the littoral current. Since once in suspension, heavy mineral particles have the tendency to settle faster than lighter particles, the result will be a decrease in the concentration of heavy minerals in the direction of littoral drift. The third factor, i.e., wave refraction patterns, gives a good indication of the direction of sand drifting along a coast since it is agreed that the littoral drift is caused by the energy component of waves breaking at an angle to the shore. Some geological observations will also be considered, wherever possible, to help in determining the direction of littoral drift.

In the samples analyzed for both thorium and heavy minerals, it was found that both surface and deep samples (one foot deep) have the same trend (Fig. 7). The beaches under study are variable beaches (Trask, 1958). They vary not only from one season to another, but also from place to place on any given beach at any given time. The chief seasonal variations in individual beaches are in grain size, sorting, height of berm, and position and shape of the foreshore. Some of the beaches always have cusps, others never, and some have cusps sometimes and not at other times. Though no consistent pattern is indicated for all beaches, most of the beaches build up in width during summer and erode during winter. However, as wave height varies from one day to another, the beaches may build or erode at any time. From the above discussion on variability of beaches, the sand samples analyzed will be considered to represent conditions during which they were collected, i.e., summer conditions. Consequently the samples analyzed will indicate the direction of littoral drift during the summer. This may agree with the predominant direction of drift for some localities and may not agree for others.

The predominant direction of drift along the part of the coast under study is generally considered to be from north to south. This is based on analyses of wave refraction diagrams (Fig. 15) drawn for the predominant waves in this area which come from W.N.W. with a wave period of 12 seconds (National Marine Consultants, 1960). Actually such refraction diagrams represent both the predominant and summer conditions, since wave conditions for both are very similar (National Marine Consultants, 1960).

A. TO STUDY THE DIRECTION OF LITTORAL DRIFT ALONG A REACH OF THE CALIFORNIA COAST

1. From north of the Russian River mouth to Bodega Head (Fig. 8)

This reach includes the beach from Russian Gulch to the Russian River mouth (samples 1 to 5). The Russian River (samples 8 to 11), Bodega Head south of the Russian River mouth (samples 6 and 7), Shell Beach (sample 12), Wright Beach, Gleason Beach, Arched Rock Beach, and Salmon Creek Beach (samples 13, 14, 15, 16, respectively).

FIG. 7 NUMBER AND LOCATION OF SAMPLES, THEIR THORIUM AND HEAVY MINERALS CONCENTRATION

HYD-8714

FIG. 8 NUMBER AND LOCATION OF SAMPLES FROM NORTH AT THE RUSSIAN RIVER MOUTH TO BODEGA HEAD, THEIR THORIUM AND HEAVY CONCENTRATIONS, AND THE DIRECTION OF LITTORAL DRIFT.

HYD-8715

For the part of the coast north of the Russian River mouth, though the refraction diagrams indicate a southward drift, the concentrations of both thorium and heavies did not show any consistent significant decrease. The concentration of thorium and heavy minerals varied along the coast from 15 to 25 ppm. and from 56 to 59 percent, respectively, without any consistent trend. The littoral drift in this part of the coast is believed to have a reversal in direction.

The Russian River samples showed a thorium concentration of 14 to 17 ppm. upstream from the junction with Austin Creek which has a concentration of 7 ppm. and 19 ppm. downstream from Austin Creek (Fig. 8). Thorium found on the beaches just north and south of the Russian River mouth probably is brought to the coast by the Russian River as it flows through thorium-rich granite rocks.

South of the Russian River mouth the concentration of thorium and heavy minerals decreases gradually and consistently from 15 ppm. and 83 percent for sample 6, to zero ppm. and 3 percent for sample 12 at Shell Beach (Fig. 8). This indicates a southward direction of littoral drift and confirms the conclusion from the analysis of the wave refraction diagrams.

For the part of the coast from Wright Beach south to Salmon Creek Beach, the concentration of thorium increased suddenly from zero at Shell Beach to 23 ppm. at Wright Beach. This is believed to be due to the sediments brought to the coast by some small streams which enter the coast between Shell Beach and Wright Beach (samples 12 and 13, respectively) and which pass through thorium-rich granite rocks. The 23 ppm. thorium concentration for sample 13 at Wright Beach decreases gradually to 17 ppm. (sample 16) at Salmon Creek Beach. Although the concentration of heavy minerals does not have significant differences, both the thorium concentration and wave refraction diagram suggest a southward direction of drift for this part of the coast.

2. From Bodega Head to Tomales Point (Fig. 9)

Bodega Head and Tomales Point are a continuation of the same geologic formation. The direction of sand drift in Bodega Bay depends on the local conditions. The samples collected and analyzed for Bodega Bay (samples 17 to 21) showed a general decreasing trend in both the concentration of thorium and heavy minerals in a northwestward direction. The concentration of thorium decreased from 30 ppm. for sample 21 to 9 ppm. for sample 17; also the percent heavy minerals decreased gradually from 11 to 2 percent for the same two samples. This suggests a northwestward direction of littoral drift during the period when the samples were collected (summer season). However, the great preponderance of chert and greenstone among the pebbles on Point Reyes Beach indicates that most of the beach material comes from the mainland east of the Point Reyes Peninsula, because no rocks of this character

are found on the Peninsula. This means that these pebbles in some way have been transported across the mouth of Tomales Bay in water 5 to 10 feet deep (Trask, 1958). Wave refraction diagrams also indicate a southward direction of drift. In conclusion it is believed that littoral sand movement in Bodega Bay is subject to reversals in direction.

3. Point Reyes Beach (Fig. 10)

Point Reyes Beach is a long straight beach. The refraction diagram drawn for W.N.W. waves with a period of 12 seconds (Fig. 15) shows that the direction of wave approach is parallel to the shore. However, waves approaching the shore from the north or south of the W.N.W. direction will result in a southward or northward littoral drift, respectively.

Samples analyzed for the Point Reyes area include sample 22 at McClures Beach and samples 23 to 26 at Point Reyes Beach. The concentration of thorium for McClures Beach is 62 ppm. This relatively high concentration is attributed to the thorium-rich granite rocks which outcrop at the seacoast in this area. The thorium concentration decreases gradually southward from 62 ppm. for sample 22 to 6 ppm. for sample 26 (Fig. 10). The concentration of heavy minerals also shows a southward decrease from 60 to 7 percent. This southward decrease in both thorium and heavy minerals concentrations suggest a southward direction of littoral drift. However, the presence of a few rounded pebbles of acid porphyry suggests the migration of material from Point Reyes (Trask, 1958).

In conclusion, it is believed that sand movement along Point Reyes beach is subject to reversals in direction. This confirms the conclusion derived from a study of the wave refraction diagrams for this beach, since waves approaching from the north will result in a southward littoral drift while waves approaching from the south will result in a northward drift.

4. Drakes Bay (Fig. 10)

Except for sample 27 at the southwest end of Drakes Bay, a significant gradual eastward decrease occurs in both the concentrations of thorium and heavy minerals (Fig. 10). The thorium concentration decreases from 215 ppm. for sample 28 to 16 ppm. for sample 32. The heavy minerals concentration decreases from 43 to 2 percent for the same samples. The source of high concentration of thorium in this area is believed to be the thorium-rich granite rocks which outcrop at the seacoast near location 28. This thorium is then diluted as it moves eastward. The decrease in both thorium and heavy mineral concentrations to the east and the wave refraction diagram pattern all suggest an eastward direction of littoral drift in Drakes Bay. The southwestward decrease in both thorium and heavy mineral concentrations for sample 28 to 27 (Fig. 10) is explained as follows: When a source of material enters the shore at a point, wave action will tend to dilute this material on both sides of the point source. It has also been observed in

FIG. 9 NUMBER AND LOCATION OF SAMPLES FROM BODEGA HEAD TO TOMALES POINT, THEIR THORIUM AND HEAVY MINERALS CONCENTRATION, AND THE DIRECTION OF LITTORAL DRIFT.

HYD-8716

FIG. 10 NUMBER AND LOCATION OF SAMPLES FOR POINT REYES BEACH AND DRAKES BAY, THEIR THORIUM AND HEAVY MINERALS CONCENTRATION, AND THE DIRECTION OF LITTORAL DRIFT.

HYD-8717

tracer experiments (Russell, 1961) that there always is some dispersion and spreading of the tracer material in a direction opposed to the net drift. The eastward direction of littoral drift for Drakes Bay has also been suggested by Trask (1958) where he observed that though the material at Drakes Cove gives no indication of the source of material, the presence of porphyry pebbles indicates an eastward direction of drift.

5. Bolinas Bay (Fig. 11)

It is believed that naturally radioactive thorium is added to the coast of Bolinas Bay from thorium-bearing granite rocks which outcrop at the seacoast at the southwest end of the bay. This material is then diluted in an eastward direction. This is confirmed by the decrease in the concentration of both thorium and heavy minerals. Thorium concentration decreased from 142 ppm. for sample 33 on the southwest side of Bolinas Bay to 30 ppm. at Stinson Beach (Fig. 11). Concentrations of heavy minerals decreased from 5 to 0.4 percent for the same locations. Wave refraction diagram strongly suggests an eastward direction of littoral drift. In conclusion, based on the eastward decrease in thorium and heavy mineral concentrations and on the wave refraction diagram, it is believed that the littoral drift direction for Bolinas Bay is eastward. This is also confirmed by the presence of numerous pebbles of Miocene rocks along Stinson Beach, which can only come from the west. These pebbles have been transported across the mouth of Bolinas lagoon in water at least 5 feet deep (Trask, 1958).

6. San Francisco Bar (Fig. 11)

Offshore bottom samples taken in the vicinity of the San Francisco Bar show a very high concentration of thorium and heavy minerals on the top of the bar as indicated by sample 68 which has 162 ppm. thorium and 27 percent heavy minerals and by sample 65 which has 180 ppm. thorium and 44 percent heavy minerals. The concentration of thorium and heavy minerals decreases considerably on both sides of the bar as shown in Fig. 11.

A high concentration of both thorium and heavy minerals is also found in sample 48 in front of Fleischhacker Zoo at Ocean Beach (112 ppm. and 36 percent). The concentration decreases considerably both northward and southward of Fleischhacker Zoo (Fig. 12). The very high concentration of thorium and heavy minerals for samples 68, 65, and 48 which are from the top of the San Francisco Bar, and the considerable decrease in these concentrations on both sides of the bar suggests very strongly the migration of material from the north to the south along the top of the bar. This material then enters Ocean Beach in front of Fleischhacker Zoo and is diluted in both a northward and southward direction. This is clearly demonstrated by the extensive sampling and analyses of Ocean Beach sands as explained in the following paragraph.

7. Beaches south of Golden Gate (Fig. 12)

Extensive sampling was made of Ocean Beach to determine the location where the littoral material migrating from north of the Golden Gate enters the beach. Both surface and deep samples analyzed for thorium and heavy mineral concentrations for both size fractions 74 to 177 micron and 125 to 250 micron showed a high concentration for the beach in sample 48 at Fleishhacker Zoo. This high concentration decreased gradually and consistently southward from the source point at Fleishhacker Zoo (sample 48) to sample 53 near Sharp Park (Fig. 12).

The increase in concentration for samples 54 to 58 is attributed to sediments brought by several small streams which enter the coast in the vicinity of Sharp Park and Rockaway Beach. These gullies flow through thorium-rich granite rocks. The high increase in thorium concentration for sample 59 near Point San Pedro is attributed to the thorium-bearing granite rocks which outcrop at the seacoast in this area.

The consistent gradual southward decrease in both the concentrations of thorium and heavy minerals for samples south of Fleishhacker Zoo indicate a southward direction of littoral drift during the summer for this part of the coast. The less consistent northward decrease in concentrations for samples north of Fleishhacker Zoo may suggest a northward drift for this part of the coast.

Ocean Beach is a fairly straight beach similar to Point Reyes Beach. Refraction diagrams drawn for the predominant wave conditions show that waves approach parallel to the shore. If waves along this part of the beach come in at an angle from the south or the north, they should produce a southward or northward drift, respectively. Frequently the waves along this part of the beach come in at an angle from the south (Trask, 1958). Such waves should produce a northward littoral current, which should transport sand toward the north.

Fig. 16 shows the direction of littoral drift along the reach of the California Coast between the Russian River and Point San Pedro based on the above analysis. The source of radioactive material (streams or rocks) as well as the concentration of thorium and heavy minerals at different localities are also indicated.

B. TO STUDY THE VARIATION IN THORIUM CONCENTRATION ALONG A BEACH PROFILE (Fig. 13)

The profile chosen for analysis in the vicinity of Location 30 on Drakes Bay (Fig. 10) showed a fairly constant concentration of both thorium and heavy minerals for a considerable distance on both sides of the mid-tide point. This is a fortunate condition since it shows that no significant error will be encountered if samples are collected exactly at mid-tide or several feet onshore or offshore from the point of mid-tide (Fig. 13).

FIG. 11 NUMBER AND LOCATION OF SAMPLES FOR BOLINAS BAY AND SAN FRANCISCO BAR, THEIR THORIUM AND HEAVY MINERALS CONCENTRATION, AND THE DIRECTION OF LITTORAL DRIFT.

HYD-8718

FIG. 12 NUMBER AND LOCATION OF SAMPLES SOUTH OF THE GOLDEN GATE, THEIR THORIUM AND HEAVY MINERALS CONCENTRATION, AND THE DIRECTION OF LITTORAL DRIFT.

HYD-8719

FIG. 15 WAVE REFRACTION DIAGRAMS FOR THE REACH UNDER STUDY
HYD-8720

FIG. 16 THE DIRECTION OF LITTORAL DRIFT AND THE SOURCES OF THORIUM (STREAMS AND ROCKS) FOR THE REACH UNDER STUDY
HYD-8721

The samples for this profile were collected during the low tide period on June 7, 1961. The average concentration for thorium and heavy minerals in the vicinity of the point of mid-tide were found to be about 25 ppm. thorium and 19 percent heavy minerals which agrees with the results obtained for sample 30 which has a thorium concentration of 32 ppm. and 18 percent heavy minerals. Sample 30 was taken at mid-tide during the period between June 15 and 18, 1961.

Though little is known at present about sorting of sedimentary beach material due to its selective onshore-offshore transport by wind or shallow water waves (Ippen, 1955), the increase in the concentrations of heavy minerals and thorium near the backshore of the profile under study may be attributed to wind sorting as it is generally observed that black sands tend to concentrate on the backshore of beaches; however, this phenomenon needs to be further investigated.

C. TO STUDY THE VARIATION IN THORIUM CONCENTRATION WITH TIME AT A SPECIFIC LOCATION ON A BEACH (Fig. 14)

The samples analyzed for the part of Ocean Beach in front of Fleishhacker Zoo were collected at mid-tide during the period between June 17 and December 18, 1961. These samples showed a lower thorium concentration during the fall season than during the summer season (Fig. 14). This may be because during the fall season waves along Ocean Beach frequently come in at an angle from the south. Such waves should produce a northward current, which would transport sand northward. If sand is transported toward the north at Ocean Beach, the concentration of thorium at Fleishhacker consequently will decrease, since it is believed that the reason for high thorium concentration is material migrating from the north along the top of the San Francisco Bar and entering Ocean Beach in the vicinity of Fleishhacker Zoo.

SUMMARY AND CONCLUSIONS

Tracers have already shown themselves to be most useful in situations where there is uncertainty about the movement of sediments. There are beaches for example where there is doubt concerning the direction of littoral drift and where a tracer experiment which might reveal the direction of movement would be justified.

The method of using radioactive thorium as a tracer for sand movement along a portion of the California Coast presented itself in that there are discrete places along the coast where rivers flowing through thorium-rich granite outcrops reach the coast or where the thorium-rich granite itself crops at the seacoast.

This method of assaying for naturally radioactive thorium as a means of detecting the direction of drift of sand along a seacoast was investigated and applied to the reach of the Coast of California from the Russian

River mouth to Point San Pedro. The method proved to be very efficient for qualitative results and rather simple compared to mineralogical analyses.

The difficulties in this technique are:

1. The low counting rate for thorium and uranium at high energy levels (2.63 and 1.86 mev. respectively) to avoid the interference from the 1.46 mev. peak from K^{40} in the potassium minerals. This was avoided by assaying for the heavy minerals of the sand samples separated by bromoform to get rid of the potassium minerals present and consequently counting for the 0.188 mev. peak from Ra^{226} in the uranium series and the 0.238 mev. Pb^{212} peak in the thorium series which will give a higher counting rate.

2. The method requires that the sand samples analyzed should be in good contact with the scintillation crystal in order to obtain sufficient counts for analysis, but the thickness of the sample layer must not be so great that the photopeaks are masked by Compton scattered radiation from within the sample. In order to get good contact between the sand samples analyzed and the scintillation crystal, the samples should be placed around the crystal, but this will require a large sample size which is not available in this study since the weight of the heavy minerals assayed is generally less than 10 grams. For this reason the heavy mineral samples were placed on the top of the scintillation crystal and correction for the sample thickness was made as indicated in Appendix III.

3. Since the gamma-rays concerned are from natural sources of low activity it was necessary to minimize the total count-to-background ratio, which was done by working in a laboratory of a constant low background.

The three factors considered in determining the direction of littoral sand drift along the reach of the California Coast under study are:

1. The concentration of thorium (in parts per million) in the heavy minerals of a limited size fraction of the sand samples analyzed.

2. The percent of heavy minerals in the same size fraction used in (1).

3. Wave refraction diagrams.

A decrease in the concentration of thorium and heavy minerals from the source area indicated alongshore drift in the direction of decrease of both parameters. In order for the decrease in concentration of thorium and heavy minerals to indicate the direction of littoral drift, this decrease in concentration should be due to progressive sorting caused by the alongshore current on the beach sands. For this reason the effect of local sorting on the beach sands should be eliminated. This has been done by comparisons between sample concentrations for a very small fraction, i.e., 74 to 177 microns. Wave refraction patterns give a good indication of the

direction of sand drifting along a coast since it is agreed that the littoral drift is caused by the alongshore energy component of waves breaking at an angle to the shore.

Precision of the method depends on the abundance of thorium in the sand samples. Comparisons of composition from one sample to another can at best indicate genesis if the changes are large. For example the virtual absence of thorium in one sample and the presence of say 15 ppm. thorium in an adjacent sample, strongly suggests a local source of thorium. On the other hand, if 15 ppm. of one sample is thorium, and 20 ppm. of another is thorium no significant conclusion may be drawn except if we have a consistent decreasing trend from one sample to another.

Based on the distribution of beach samples and their thorium and heavy mineral concentrations and wave refraction diagrams, it is believed that the pattern of sand movement along the California Coast from the Russian River mouth to Point San Pedro takes the following form: For the part of the coast north of the Russian River mouth though the refraction diagrams indicate a southward drift, the concentrations of both thorium and heavy minerals do not show any consistent or significant decrease in any direction which suggests a reversal direction of littoral drift for this part.

South of the Russian River mouth the concentration of both thorium and heavy minerals decreases gradually and consistently in a southward direction. This indicates a southward direction of sand movement which is also confirmed by the wave refraction diagram pattern for this part.

For Bodega Bay, although a northward direction of drift is indicated by the northward decrease in concentration of both thorium and heavy minerals, the great preponderance of chert and greenstone among the pebbles on Point Reyes Beach indicates that most of the beach material comes from the mainland east of the Point Reyes Peninsula, because no rocks of this character are found on the Peninsula which shows a southward direction of drift. This is also confirmed by the wave refraction diagram pattern.

Wave refraction diagrams drawn for Point Reyes Beach for W.N.W. waves with a period of 12 seconds which represents the predominant wave condition in this part, show that the direction of wave approach is parallel to the shore. However, waves approaching the shore from the north or south of the W.N.W. direction will result in a southward or northward littoral drift, respectively, which indicates that sand movement along Point Reyes Beach is subject to reversals in direction.

For Drakes Bay the decrease in both thorium and heavy minerals concentration to the east, wave refraction diagram pattern and the presence of porphyry pebbles all indicate an eastward direction of littoral drift.

The eastward decrease in thorium and heavy minerals concentration, wave refraction diagram pattern, and the presence of numerous pebbles of Miocene rocks along Stinson Beach, which can only come from the west, all indicate an eastward direction of sand movement along Bolinas Bay.

The high concentration of both thorium and heavy minerals for the samples taken from the top of the San Francisco Bar and the respective northward and southward decrease of both these concentrations north and south the top of the bar in front of Fleishhacker Zoo at Ocean Beach, suggests very strongly the migration of material from the north to the south along the top of the bar. This material then enters Ocean Beach in front of Fleishhacker Zoo and is diluted in both a northward and southward direction.

ACKNOWLEDGEMENTS

The author expresses his appreciation and sincere thanks to Professors J. W. Johnson, P. R. Day and W. J. Kaufman for their cooperation, inspiration and guidance throughout the investigation.

Professor J. W. Johnson, who was the chairman of the thesis committee is to be acknowledged not only for his invaluable guidance but also for procuring funds necessary for the investigation.

Thanks are also due to Professor H. A. Einstein and Dr. R. B. Krone with whom the author had many interesting and informative discussions, to Dr. G. Gordon of the Department of Mineral Technology for making available the gamma-ray spectrometer and his continuous help during the experimental work.

The National Science Foundation's financial support of the work is gratefully acknowledged.

APPENDIX I

EXPERIMENTAL EQUIPMENT

The Gamma-Ray Spectrometer

The device by which gamma rays of a specific energy can be discriminated from all other gamma rays is called a gamma-ray spectrometer. It consists of:

- (1) A scintillation detector, and (2) a pulse height analyzer.

1. The scintillation detector

Scintillation counting, one of the oldest radiation detection techniques, has gone through several developmental phases. The visually detected scintillations of energetic alpha-particles absorbed in thin films of zin-sulfide crystal was first noted by Sir William Crooks and also independently by Elster and Geitel in 1903. In the 1930's the visual scintillation counter became obsolete and the next 20 years were characterized by the rapid growth and development of electronic counting techniques. Gas-filled ionization chambers in which the incident charged particles generated ion pairs were used as the basic detector. With these gas-filled systems, there are three well defined operating methods - the ionization detector, the proportional counter, and the Geiger-Muller counter. With the development of sensitive photomultiplier tubes, the scintillation counter has regained its former place in research.

A scintillation detector utilizes minute flashes of light produced when gamma emission gives up energy to atoms in a crystal, organic polymer, or organic liquid. Since there are greater densities of atoms in a solid than in a gas, the chances for collision between an incident emission and an atom are greater and give the detector a correspondingly increased efficiency. The light flashes are of short duration, and interaction at one part of the detector does not paralyze the remainder. Some of the more common devices are:

a - Thallium activated NaI Crystal

A sodium-iodide crystal with a trace of thallium produces a light flash with an intensity that is proportional to the absorbed energy. Gamma-spectrometry is possible because the intensity of the light pulses is proportional to the gamma radiation. The crystal used in this device is 5 cm. long by 5 cm. in diameter. The advantages of high efficiency and the differing response for different emission energies make this detector best suited for low counting measurements.

b - The Photomultiplier tube

The photomultiplier tube serves to convert the small light pulse it sees in the clear crystal into an avalanche of electrons which are received by the next instrument as an electrical pulse whose magnitude depends upon the energy of the initial gamma quantum.

2. The pulse height analysis

The electron pulse from the photomultiplier tube appears something like the following figure:

The maximum amplitude of the pulse corresponding to some voltage potential (say x -Millivolts) is next amplified (say to y -volts at maximum height).

Since it is difficult to measure the maximum height of this pulse when it lasts for such a brief period, the pulse is reshaped by an appropriate circuit called the widener circuit to give it an approximately rectangular shape as shown below:

The height of the widened pulse is equal to the maximum height of the pulse before it was reshaped.

The reshaped pulse is now fed into a circuit called the discriminator which has been preset to detect pulses which fall within some definite voltage range.

This voltage range is termed a window. However, in order for this circuit to operate effectively, it must measure the pulse height sometime after the maximum voltage has reached the circuit and not while the pulse is rising up to its maximum value. The pulse height must be measured at about this point.

In order to achieve this result another circuit is employed called the gate generator circuit. This circuit generates a signal and sends it to the discriminator which is measuring the height of the pulse. The generation of this signal in the gate generator occurs at the first sign of a pulse going to the discriminator from the amplifier, but this gate signal does not arrive at the discriminator until shortly after the pulse, whose height is to be measured, has reached the discriminator and has had time to rise up to its maximum potential. The pulse height measuring circuit, i.e., the discriminator, will not work until the gate signal has arrived, thus giving the pulse time to reach its maximum height. The true value of the maximum pulse height is compared with the two preset values. If the pulse height is greater than the lower preset voltage, the threshold, but not greater than the upper one, threshold plus window, it causes a uniform pulse signal to be sent on to the scaling unit, and one quantum of gamma radiation, whose energy falls within the energy range represented by the window, has been detected. This energy range can be found after calibration of the spectrometer. Pulses having heights less than the lower preset voltage or higher than the upper preset voltage are not recorded for this particular window.

The gamma-ray spectrometer used in this study is a 3-channel Pedersen electronic model (Figs. 17, 18).

FIG. 17 COMPONENTS OF A 2-CHANNEL
GAMMA-RAY SPECTROMETER

FIG. 18 GENERAL VIEW OF THE GAMMA-RAY
SPECTROMETER USED

APPENDIX II

ADJUSTING THE GAMMA-RAY SPECTROMETER

In this study only 2 channels were adjusted so that the upper channel counts at the 0.188 mev. uranium peak and the lower channel counts at the 0.238 mev. thorium peak for the heavy minerals assayed. There was no need to adjust the third channel to count at the 1.46 mev. potassium peak, since it was eliminated by separating the heavy minerals from the sand sample using bromoform.

The method used to obtain the gamma ray spectrum graphs used to illustrate this study may be of some interest. Instead of lowering the bias on a pulse gating circuit as in the usual method of sweeping the gamma ray spectrum with a pulse height analyzer, the bias on the gating circuit was held constant. While holding the pulse gate at a fixed level, the voltage on the photomultiplier in the scintillation detector was linearly increased with respect to time. The output pulse from the gate was fed to a linearly moving graphic recorder. Although this method results in a logarithmic spacing of the photon energy on the graph, good resolution throughout the whole gamma spectrum is obtained.

Adjustment outline

1. Plot the relationship between anode volt dial and photomultiplier scale (Fig. 19).
2. Plot the spectra for the standard samples (Fig. 20).
3. Plot the energy of the photon peak for the standards (Fig. 21) vs. the anode dial reading at which the peak appears which yields a straight line on a semi-logarithmic paper. Such a graph facilitates the determination of the energies of photon peaks.
4. Ready the spectrometer by setting all dials and adjustments in the proper places.
5. Place the calibrating sample (Cs 137) in the machine and find the voltage dial setting at which the big peak is centered on the lower channel.
6. Leave the voltage dial alone and adjust the attenuators on the upper channel until it is also centered on the same peak as the lower channel.
7. With both channels exactly centered on the peak, adjust the channel width on the upper channel until it counts at the same rate as the lower channel.

FIG. 20 GAMMA-RAY SPECTRA FOR STANDARDS

FIG. 21 RELATIONSHIP BETWEEN THE ENERGY OF THE PHOTON PEAK AND THE ANODE DIAL READING AT WHICH THE PEAK APPEARS.

FIG. 22 Th AND Ur PEAKS COUNTING AT THE SAME DIAL READING

8. Place a thorium sample in the machine and find the voltage dial setting at which the lower channel is centered on the 0.238 mev. peak.

9. Leave the voltage dial alone and place an equilibrium uranium sample in the machine. Center the upper channel on the 0.188 mev. peak by means of the attenuators.

10. Check the upper and lower channels to be sure that they both reach a maximum peak count on the same voltage dial setting (Fig. 22). Any discrepancies are corrected by means of the channel calibration dials.

11. The channel counts and ratios are corrected with the assays by means of standard ores.

APPENDIX III
CORRECTION FOR SAMPLE SIZE

When the thickness of the sample is great, the photopeaks are swamped by Compton-scattered radiation from within the source. It was found that for a sample weight of more than 10 grams, correction should be made by introducing a correction factor C which was obtained as follows:

1. Increasing weights of heavy minerals (from the same sand sample) were assayed and counted (Table 1).

The correction factor C = maximum counts per gram weight of sample
$$= \frac{C_m}{C}$$
 counts per gram weight of sample was plotted against the weight of the sample (Fig. 23).

2. A weight of 11 milligram thorium oxide (THO) was added to increasing weights of heavy minerals from the same sample used in(1), assayed and counted on both channels. The net counting due to the addition of thorium oxide (THO) to the heavy minerals was plotted against the weight of heavy minerals (Fig. 24).

3. The net counting from 11 milligram thorium oxide (THO) when assayed without the addition of any heavy minerals was recorded.

4. For step 2 above, the correction coefficient C was calculated for different weights of the heavy minerals and was found to check well with that of Fig. 23. For this reason, the correction coefficients from Fig. 23 were used in correcting counts for samples having a weight of more than 10 grams.

BEACH EROSION BOARD, C.E., U.S. ARMY, WASH., D.C.

LITTORAL STUDIES NEAR SAN FRANCISCO USING TRACER

TECHNIQUES by Adel M. Kamel, November 1962

86 pp., 24 illus., 6 tables, and 4 appendices

TECHNICAL MEMORANDUM No. 131

UNCLASSIFIED

1. Sed. Transport by waves & currents
2. Tracers - Radioactive
3. California - Littoral drift
- I. Kamel, A. M.
- II. Title

A method of assaying naturally radioactive thorium for detecting the direction of littoral drift along a coast was investigated and applied to the California coast from the Russian River mouth to Point San Pedro. The method proved to be very quick for qualitative results and rather simple compared to mineralogical analysis. The method involved collection of surface and deep samples along the coast under study. Heavy minerals for a limited size fraction of the sand samples were separated and radioactivity present counted by use of a 2-channel gamma-ray spectrometer. One channel was adjusted on the 0.238 Mev. peak from Pb^{212} in the thorium series and the other on the 0.118 Mev. peak from Ra^{226} in the uranium series.
