 McMurdo Station Hydrocarbon-Contaminated Soil"

Abstract

Hydrocarbon-contaminated soil is distributed heterogeneously at McMurdo Station, Antarctica, which has served for over 60 years as the logistics hub for the U.S. Antarctic Program. Here we investigated the treatability of McMurdo Station's contaminated soil with chemical oxidation. Our study collected five soil samples in 2018 and 2019, of which two contained high levels (>100 mg/kg) of total petroleum hydrocarbons (TPH) suitable for the treatability study. One soil (ITC) was characterized by 1250 mg/kg of predominantly midrange (n-C8 to n-C16) hydrocarbons, and the other (Soil Pile) was characterized by 3500 mg/kg of predominantly heavy molecular weight ($>n$ -C21) hydrocarbons. We investigated the treatability of these soils with both Fenton's Reagent (pH < 3 with Fe^{2+}) and modified Fenton's Reagent (chelated Fe^{2+}), each with hydrogen peroxide concentrations of 3% and 10%. Soil slurries were placed on a shaker table at 100 rpm and 4°C for up to 21 days. TPH concentrations were reduced by approximately 50% for ITC; however, the oxidative treatments did not out-perform controls. All treatments and controls yielded no significant reduction in Soil Pile TPH. Poor performance by these chemical oxidation treatments indicates that remediation of hydrocarbons at these sites may require further soil processing in combination with chemical oxidation or alternative treatment technologies.

Preface

This study was conducted for the National Science Foundation (NSF), Office of Polar Programs (OPP), Antarctic Infrastructure and Logistics Program (AIL), under Project EP-ANT-18-80, “Hydrogen Peroxide / Fenton’s Reagent Treatability Study of McMurdo Station Hydrocarbon-Contaminated Soil.” The technical monitor was Ms. Margaret Knuth, Operations Manager, NSF-OPP-AIL, U.S. Antarctic Program.

The work was performed by the Biogeochemical Sciences Branch (BSB) and the Force Projection and Sustainment Branch (FPSB) of the Research and Engineering Division, U.S. Army Engineer Research and Development Center, Cold Regions Research and Engineering Laboratory (ERDC-CRREL). At the time of publication, Dr. Gina Ralph was Acting Chief, BSB; Mr. Justin Putnam was Acting Chief, FPSB; and Mr. J. D. Horne was Division Chief. The Deputy Director of ERDC-CRREL was Mr. David B. Ringelberg, and the Director was Dr. Joseph L. Corriveau.

The authors gratefully acknowledge Ms. Anne Hellie and Ms. Spring Wood, formerly with Leidos, Antarctic Support Contract (ASC), for the report on their Fenton’s Reagent study on the McMurdo soil pile. The authors also acknowledge the assistance by ASC staff in collecting, packaging, and shipping samples.

COL Teresa A. Schlosser was Commander of the ERDC, and Dr. David W. Pittman was the ERDC Director.

1 Introduction

1.1 Background

McMurdo Station, located on the Hut Point Peninsula, Ross Island, Antarctica, serves as the logistics hub for the U.S. Antarctic Program (USAP), which is managed by the National Science Foundation (NSF). McMurdo provides research and science support across the continent of Antarctica, including to Amundsen-Scott South Pole Station. McMurdo Station's existing facilities were constructed on an outcrop of barren volcanic rock modified to form a series of flat fill platforms (Affleck et al. 2017). Initially established in 1955, McMurdo Station has grown to include approximately 100 buildings, three runways, and a helicopter pad.

Soil contamination by fuel and lubricating oil spills occurs in patches across McMurdo Station. Areas of high contamination, characterized by total petroleum hydrocarbons (TPH) greater than 500 parts per million (ppm), are concentrated near fuel storage tanks (formerly used and current), refueling stations, vehicle maintenance facilities, a landfill, and vehicle parking areas (Klein et al. 2012). High molecular weight petroleum compounds (HMW) are present primarily in areas where vehicles are parked and are not associated with fuel tanks and refueling stations (Klein et al. 2012). The dominant fuels used at McMurdo since its construction have been JP-5, JP-8, AN-8 (a special low-freezing-point fuel), and MOGAS (unleaded gasoline; Klein et al. 2008; Haehnel et al. 2017). Between 2005 and 2015, USAP purchased approximately 19 million liters per year total of JP-5, AN-8, and gasoline (Haehnel et al. 2017). Unlike some other Antarctic bases, diesel is not a primary fuel at McMurdo (Aislabie et al. 2004).

The fate and transport of hydrocarbons depend on the type of fuel spilled and the soil structure. Gasoline and lighter components of the jet fuels JP-5, JP-8, and AN-8 readily volatilize at the surface and, due to their lower viscosity, are also more mobile than diesel and oils (Aislabie et al. 2004). Hydrocarbon permeation in soil overlying permafrost may be limited to the active layer, as permanently frozen soil acts as a physical barrier in the absence of any cracks or fissures (Aislabie et al. 2004). However, a suspected hydrocarbon layer in the ice-cemented substrate underneath frozen soil at McMurdo Station was identified in soil pits and cores (Affleck et al. 2017) and in ground-penetrating-radar surveys (Campbell et al. 2018). Runoff

measured from major McMurdo drainages during a period of thaw did not yield any petroleum hydrocarbon concentrations above the detection limits (40–300 µg/L;* Affleck et al. 2014), which indicated contaminants were relatively adsorbed in place and minimally displaced by snowmelt.

Current building development on McMurdo station needs to manage potentially contaminated soils and to find inexpensive management solutions compared with off-site disposal (NSF 2019). Unfortunately, in cold regions like McMurdo Station, hydrocarbons can persist and accumulate over long periods of time due to low biological activity, low soil moisture, low nutrient levels, and slow reaction kinetics (Affleck et al. 2017; Aislabie et al. 2004; Eriksson et al. 2001; Klein et al. 2012). This slow natural attenuation explains elevated TPH concentrations near previously removed fuel tanks at McMurdo (Klein et al. 2012) and hydrocarbon off-gassing from soil pits (Affleck et al. 2017) and soil cores (Fenwick and Winkler 2016; Fenwick et al. 2017). At Old Casey Station, Antarctica, biodegradation stimulated with added nutrients resulted in only a 15% decrease in soil diesel concentrations (Ferguson et al. 2003).

Chemical oxidation has been a successful method for remediating petroleum-contaminated soil at more temperate locations. Though there are many chemical oxidants, Fenton's Reagent has been among the most popular. Fenton's Reagent involves the reaction of hydrogen peroxide (H_2O_2) with Fe^{2+} to form the reactive hydroxyl radical and Fe^{3+} . Classic Fenton's Reagent uses 0.03% H_2O_2 , but field applications require higher concentrations (Interstate Technology and Regulatory Council 2005). Typically, acidic conditions improve TPH degradation by reducing Fe^{3+} to the more soluble Fe^{2+} (Watts 1992). There have been numerous modifications to Fenton's Reagent, which in many cases use chelates to improve iron solubility and availability without the need for acidic conditions (e.g., Kakarla et al. 2002). Lab-scale studies on petroleum-contaminated soil in temperate regions typically observe 50% or greater reduction in TPH with Fenton's Reagent and Modified Fenton's Reagent treatments (Lu et al. 2010; Mater et al. 2007; Tsai and Kao 2009).

* For a full list of the spelled-out forms of the units of measure and chemical elements used in this document, please refer to *U.S. Government Publishing Office Style Manual*, 31st ed. (Washington, DC: U.S. Government Publishing Office, 2016), 248–252, 265, <https://www.govinfo.gov/content/pkg/GPO-STYLE-MANUAL-2016/pdf/GPO-STYLEMANUAL-2016.pdf>.

At low temperatures, decreased kinetics may inhibit Fenton's Reagent performance. However, a recent study found complete degradation with H_2O_2 treatment on Arctic soil at 4°C (Sherwood and Cassidy 2014). To date, only one published study has examined chemical oxidation of petroleum-contaminated soils in Antarctica. Ferguson et al. (2004) conducted a field trial on diesel-contaminated soil at Old Casey Station and did not observe any degradation using relatively concentrated H_2O_2 (30%).

1.2 Objectives

The objective of this study was to determine the effectiveness of Fenton's Reagent and Modified Fenton's Reagent in reducing TPH concentrations in petroleum-contaminated soil from McMurdo Station.

1.3 Approach

This study approached treatability through lab-scale tests on sampled McMurdo soils by using four different treatments and eleven time steps. This method attempted to simulate realistic remediation conditions possible at McMurdo Station by using minimal sample preparation, relatively safe-for-handling reagent concentrations, and site-relevant ambient temperatures.

2 Methods

2.1 Soil sampling and shipment

For this study, Antarctic Support Contract collected samples from five sites at McMurdo Station in 2018 and 2019 (Table 1). Samples from two sites (Red Fines and Gray Fines) were expected to be clean as these materials are used for current construction activities. Three sites sampled had expected hydrocarbon contamination based on usage history, odor, and appearance (Figure 1). At the Vehicle Maintenance Facility (VMF), soil was collected from the surface outside Bay 7 (VMF7) where vehicle fluids may have accidentally been released. At the Information Technology and Communications (ITC) building's first foundation footer (ITC F1), suspected clean fill material was underlain by a darker layer with a hydrocarbon odor—the sample was collected from the darker layer. The Soil Pile was composed of material collected from spills that occurred during 2018 and early 2019. Duplicate samples were collected using a metal scoop and 1 L glass jars with polytetrafluoroethylene-lined caps. Sample containers were filled to have minimal headspace.

The VMF, Red Fines, and Gray Fines samples were initially stored in an unrefrigerated storage container at McMurdo Station and may have experienced infrequent periods of temperatures above 10°C in austral summer months. The ITC F1 and Soil Pile samples were stored in a –20°C freezer upon collection. All samples were shipped frozen, to minimize in-transport degradation, from McMurdo to the U.S. Army Cold Regions Research and Engineering Laboratory (CRREL) via Port Hueneme, California. Samples arrived at CRREL on 4 April 2019 and were immediately placed in a cold room at approximately –20°C.

Table 1. Soil-sample descriptions.

Sample	Sampling Date	Description
VMF7	2/13/2018	Location outside Bay 7 with historic spills; no odor
Red Fines	2/13/2018	Clean red fines used for construction and operations
Gray Fines	2/13/2018	Clean gray fines used for construction and operations
ITC F1	1/9/2019	ITC First Footer location near the entrance to the mechanical equipment center; strong odor
Soil Pile	1/9/2019	Soil collected from station spills during the 2018–2019 season; light odor, may contain glycol

Figure 1. Sampled sites where hydrocarbon contamination was suspected.

2.2 Sample processing

We removed soil samples from the cold room and transferred them to refrigerators (4°C) to thaw for two days. Thawing was required to disaggregate soil grains and to enable representative subsampling of the material. Entire thawed soil samples were passed through a 2 mm stainless steel sieve in a refrigerated room (~4°C). The two sieve fractions were isolated and stored in separate glass jars. Approximately 10 g subsamples were collected from thawed <2 mm soil by spreading the sample out to an approximately 1 cm deep layer on aluminum foil in a fume hood and collecting 20–40 evenly spaced increments into 40 mL vials.

2.3 Treatability study design

The study simulated remediation conditions that would be relatively feasible to create at McMurdo Station during austral summer, including non-homogenized soil, low reagent-to-soil ratios (1:2), safe-to-handle reagents, minor amounts of agitation, and a cool temperature (~4°C). The studied temperature was chosen to ensure reagents remained in the liquid state, particularly the iron catalyst. The freezing point of H₂O₂ varies significantly with its concentration, for instance –2°C at 3 wt%, –6°C at 9 wt%, and –23°C at 28 wt% (Foley and Giguère 1951). Our study, therefore, serves as an upper bound on degradation rates that can be achieved without intensive manipulation of soil conditions, as temperatures infrequently exceed freezing at McMurdo Station (Affleck et al. 2012).

The experimental variables investigated in this study were five different treatments and eleven reaction time steps. The experimental treatments were determined using established guidance on chemical oxidation treatments that are feasibly implemented by remedial operators in the field (Siegrist 2010). The treatments listed in Table 2 include Fenton's Reagent (FR) at 3% and 10% H₂O₂ (Fisher Chemical 30% Certified ACS) with 0.1 M Fe as iron sulfate (Fe(II)SO₄·7H₂O; Acros Organics 99+%) and sulfuric acid (H₂SO₄; Fisher Chemical Trace Metal Grade) to modify pH to 3. A modified Fenton's Reagent (MFR) consisted of 0.1 M Fe and 0.1 M EDTA* (Sigma ACS Grade 99.6%) to chelate Fe and avoid pH modification, with both a low (3%) and high (10%) concentration of H₂O₂. MilliQ deionized water (18.2 MΩ) was also tested as a control. Subsamples from each treatment group were sacrificed at 30 minutes, 1 hour, 2 hours, 4 hours, 8 hours, 1 day, 2 days, 4 days, 7 days, 14 days, and 21 days after treatment.

Table 2. Five treatment levels used in batch experiments. Volumes of pH modifier were to be determined (TBD) experimentally for each soil, discussed in Section 3.2.

Treatment	Iron/Chelate	pH Modifier	Oxidizer
FR 3%	2.5 mL 0.1 M Fe	TBD μ L 1 M H ₂ SO ₄	2.5 mL 3% H ₂ O ₂
FR 10%	2.5 mL 0.1 M Fe	TBD μ L 1 M H ₂ SO ₄	2.5 mL 10% H ₂ O ₂
MFR 3%	2.5 mL 0.1 M Fe/EDTA	-	2.5 mL 3% H ₂ O ₂
MFR 10%	2.5 mL 0.1 M Fe/EDTA	-	2.5 mL 10% H ₂ O ₂
Control	-	-	5 mL MilliQ

2.4 Treatability study procedure

The experiment began upon addition of treatment reagents to thawed soil subsamples (10 g) in a fume hood. These samples were vortexed to mix the reagents and the soil slurries, then immediately moved to a cold room (~4°C) and placed on a shaker table at 100 rpm (revolutions per minute). Caps were placed loosely on subsamples to allow evolved gases to vent without breaking the vials. At each time step, soil slurries were removed from shaking and extracted with 20 mL of n-hexane (Fisher Chemical Optima 95%). The extracts were vortexed for 30 seconds, centrifuged at 1000 rpm for 1 minute, and the upper organic phase syringe filtered (0.45 μ m Millex-FH) into autosampler vials, which were then refrigerated at approximately 4°C until analysis. Samples were analyzed within 3 days of extraction.

* Ethylenediaminetetraacetic acid, a chelate

Rapid sample extraction was required to capture TPH concentrations at short time periods. Addition of anhydrous sodium sulfate was tested to chemically dry the samples and effectively stop the reaction. Approximately 12 g and 10 g of salt were required for ITC F1 and Soil Pile, respectively. However, drying created an impermeable cap that prevented hexane from interacting with the dried soil during extraction, evidenced by low TPH recoveries (<20%). Instead, the method of rapid extraction, centrifugation, and filtration produced TPH concentrations within the subsampling variability of the raw untreated soils and was subsequently used for the treatability study.

2.5 Sample analysis

Sample extracts were measured for TPH by gas chromatography with a flame ionization detector (GC-FID; Agilent 6890A). The column was an Agilent HP Ultra2 25 m × 0.200 mm with 0.33 µm film thickness; the injection volume was 1 µL; the splitless inlet was set at 285°C; H₂ carrier gas was set at 2 mL/min; and the detector was set at 325°C with 40 mL/min H₂, 450 mL/min air, and 45 mL/min N₂. The oven temperature program was 30°C from 0 to 3 minutes followed by a linear ramp to 300°C at 15°C/min and held at 300°C for 5 minutes. The total run time was 26 minutes. TPH was determined by integrating the peak area from n-C8 to n-C36 retention times (4.72 to 25.80 m) using a straight baseline. For samples containing prominent late-eluting peaks, an HMW peak (Klein et al. 2012) was also integrated from 18.8 to 21.0 minutes. Soil moisture was determined by drying subsamples at 110°C overnight, and concentrations were corrected to report TPH on a dry-weight basis.

Stock and spike standards combined equal parts JP-5, JP-8, unleaded gasoline, diesel fuel #2, and hydraulic oil analytical standards (all from Restek) to a final TPH concentration of 2250 mg/L. Calibration standards were made by diluting the stock standard to final concentrations ranging from 20 to 2250 mg/L. A five-point calibration, a boiling point / carbon number standard (Restek; n-C6, n-C8, n-C10, n-C12, n-C16, n-C21, n-C28, n-C35, n-C36), and an independent calibration verification (Restek; JP-5, JP-8, diesel #2) were run on the GC-FID daily with each batch of samples.

3 Results and Discussion

3.1 Soil characteristics

All of the soils contained a dominant proportion of >2 mm particle sizes (Table 3). This fraction is considered gravel and is not included in USDA (U.S. Department of Agriculture) soil characterization. Hydrocarbons are likely to reside between the larger surface area of the (<2 mm) soil grains, making the smaller-soil-size fraction of greater interest in this study. Further, this smaller particle size is more likely to produce subsamples with TPH concentrations that are more reproducible than those from gravel.

TPH concentrations were below the detection limit (40 mg/kg) for the Red Fines and Gray Fines soils, and they were above the detection limit but relatively low for VMF7. The GC-FID chromatograms for VMF7 were generally flat for most compounds less than n-C₂₁ but had small late-eluting peaks characteristic of HMW at McMurdo Station (Klein et al. 2012). Soil from ITC F1 and Soil Pile contained relatively high TPH concentrations of 1250 and 3500 mg/kg, respectively. GC-FID chromatograms of ITC F1 and Soil Pile highlight differing hydrocarbon sources at these sites (Figure 2). The chromatogram for ITC F1 shows a singular feature between n-C₈ and n-C₁₆ whereas the chromatogram for Soil Pile exhibits a peak between n-C₁₀ and n-C₁₆ followed by a prominent peak between n-C₂₁ and n-C₃₅. The earlier peaks in both samples are consistent with jet fuels or kerosene. The later peak in Soil Pile reflects the HMW peak found across McMurdo Station near roads and parking areas and is suspected to derive from hydraulic fluid (Klein et al. 2012). The overall high TPH concentrations from ITC F1 and Soil Pile enabled these soils to be used in the treatability study, as measurable reductions in TPH would indicate successful treatment.

Table 3. Soil particle size from sieving (whole sample) and initial TPH results for the <2 mm fraction (average $\pm$ one standard deviation) on triplicate subsamples.

Sample	>2 mm (%)	<2 mm (%)	Moisture (%)	TPH (mg/kg)
VMF7	50.7	49.3	5.3	100 $\pm$ 20
Red Fines	66.0	34.0	-	<40
Gray Fines	54.4	45.6	-	<40
ITC F1	75.0	25.0	8.8	1250 $\pm$ 90
Soil Pile	58.1	41.9	3.2	3500 $\pm$ 300

Figure 2. Representative GC-FID chromatograms for ITC F1 and Soil Pile extracts. Retention times for n-alkane marker compounds are shown in *gray*.

3.2 Study optimization

Classic Fenton's Reagent requires a sustained pH less than 3 to convert oxidized Fe(III) to Fe(II) and to drastically improve overall Fe solubility and availability. The pH measurements of 1:1 soil:water extracts shaken overnight were 7.86 and 9.37 for ITC F1 and Soil Pile, respectively. The geologic composition of the boulders, rock, and coarse-grained soils from the weathered volcanic bedrock is commonly alkaline (Affleck et al 2017; Balks et al. 2013), highlighting the need for pH modification for Fenton's Reagent treatment. Optimization samples were prepared identically to treatment samples to determine the quantity of added H_2SO_4 needed to achieve pH less than 3. Table 4 shows that adding H_2O_2 and iron sulfate alone led to a significant decrease in pH for both soil samples, but adding 90 to 210 μL of 1 M H_2SO_4 was needed to bring the pH below 3. After shaking for one day, the pH for both soils rose to between 4.6 and 4.9, depending on H_2O_2 concentration, and required additional H_2SO_4 .

Table 4. Acid addition optimization results for Fenton's Reagent treatment.

Sample	H_2O_2 (%)	t = 0		t = 1 Day with Shaking	
		pH	1 M H_2SO_4 to pH <3 (μL)	pH	1 M H_2SO_4 to pH <3 (μL)
ITC F1	3	3.8	90	4.58	420
ITC F1	10	4.1	90	4.87	210
Soil Pile	3	4.6	150	4.6	510
Soil Pile	10	4.9	210	4.9	240

3.3 Study observations

Immediately following addition of H_2O_2 , some sample containers became warm to hot to the touch from exothermic reactions occurring. Bubbles of evolved gas occurred throughout the 21-day study and were also noted in the aqueous layer postextraction, potentially due to oxidation of the added hexane.

The experiments were conducted in cold rooms that were set to 4°C but subject to variability in temperature due to the operation state and personnel ingress and egress. A temperature logger placed adjacent to the shaker table recorded air temperature over the 21-day experiments for each soil. Temperature was relatively variable from the beginning of the ITC F1 experiment until 13 August when the experiment was moved to a different cold room, marked in (Figure 3) by a short-lived (<30 minute) increase in temperature to 11°C . Temperatures were slightly cooler and less variable in the new cold room for the rest of the ITC F1 and Soil Pile experiments (Figure 3). Overall the mean temperature was 4.72°C , the median was 4.56°C , and the standard deviation was 0.97°C .

Figure 3. Air temperatures adjacent to the experiment's shaker table during the 21-day experiments. The *dashed* line represents the mean temperature.

3.4 Treatability results

Figure 4 and Appendix A present the posttreatment TPH data for the ITC F1 and Soil Pile soils. Despite observations of oxidative reactions occurring in the soils, TPH concentrations remained generally within the range of the initial pretreatment concentration until 2 days for ITC F1 and for the

entire 21 days for Soil Pile. Notable temporary out-of-trend increases and decreases in TPH are present in the time series for both soils and likely reflect subsampling variability that was not captured in the triplicate initial samples. We expected, based on the literature, effective treatment to induce a significant (>50%) and time-consistent decrease in TPH concentration (Lu et al. 2010; Mater et al. 2007; Tsai and Kao 2009).

Figure 4. Posttreatment TPH concentrations in ITC F1 and Soil Pile samples by reaction time and treatment type. The *dotted lines* represent mean ± 1 standard deviation bounds of pretreatment TPH concentrations.

For ITC F1, TPH concentrations generally decreased between 4 days and 21 days to approximately half of the pretreatment concentration for all treatments. The MFR treatments at both H_2O_2 concentrations appeared to slightly outperform the FR treatments. However, the control consistently produced lower TPH concentrations than any of the treatments. This unexpected degradation in the control samples suggests relatively rapid bio- or abiotic degradation. Experimental conditions were nonsterile, so colonization by local petroleum-degrading bacteria cannot be ruled out. Enhanced biodegradation in the control would suggest that pH or other environmental conditions in the treatments were relatively inhospitable. The low pH for the FR treatments may have inhibited biodegradation and explain its generally poor performance relative to the less acidic MFR treatments and circumneutral control. Despite the cool environmental conditions, loss to volatilization is also a possibility for this soil; however, we would expect this effect would be the same across all treatments. Overall, these results indicate that chemical oxidation had a negligible effect on petroleum-compound concentrations relative to other processes.

For Soil Pile, TPH concentrations remained generally within the subsampling variability of initial TPH concentrations for all time steps and treatments, including the control. To investigate compositional changes that may be masked by the TPH metric, Figure 5 shows the HMW portion of the chromatograms. The HMW results broadly reflect the TPH results, with generally higher concentrations early in the study but no major changes throughout the 21-day study.

Kinetic limitations by the temperature used in the study were investigated by repeating the experiment at room temperature ($\sim 20^\circ\text{C}$) for a 4-day period. Adequate soil remained for only the Soil Pile samples. Table 5 compares the results of this room temperature study. Room temperature TPH concentrations after 4 days were not consistently lower than the original experiment at 4°C after 4 days, indicating temperature was not a limiting factor in chemical oxidation of this soil.

Figure 5. Posttreatment HMW concentrations in Soil Pile samples by reaction time and treatment type. Dotted lines represent mean ± 1 standard deviation bounds of pretreatment HMW concentrations.

Table 5. Treatability results for Soil Pile at room temperature and 4 °C over 4 days.

Treatment	TPH (HMW) Concentration (mg/kg)	
	Room Temperature	4 °C
FR 3%	2900 (760)	3120 (670)
FR 10%	3060 (770)	3220 (680)
MFR 3 %	3720 (960)	2930 (600)
MFR 10%	3300 (824)	3760 (870)
Control	3930 (1050)	3300 (730)

3.5 Limitations and field-scale applicability

The negligible chemical oxidation of petroleum hydrocarbons in this study is in contrast to those reported in many bench-scale experiments and some field-scale soil experiments (e.g., Watts 1992; Watts and Dilly 1996; Kong et al. 1998; Lu et al. 2010; Mater et al. 2007; Sherwood and Cassidy 2014; Tsai and Kao 2009). In our study, temperature was not a limiting factor for at least one of the McMurdo soils, leaving the soil composition or the treatment process as a potential explanatory variable in the observed insignificant degradation. For processing, we sieved the soils only to remove gravel-sized particles, whereas other bench-scale experiments mechanically homogenized soils to smaller particle sizes (e.g., Sherwood and

Cassidy 2014; Tsai and Kao 2009; Mater et al. 2007). Homogenization increases the soil surface area and may promote the oxidative treatment to interact with contaminated soil. Field-scale homogenization is possible in an ex situ treatment but is energy intensive. We selected the strengths of H_2O_2 used in this treatability study for their relative safety in handling by field personnel; however, stronger H_2O_2 concentrations are available. A previous Fenton's Reagent study on the McMurdo soil pile used approximately 30% H_2O_2 on homogenized soil at room temperature and observed significant reductions (~97%) in TPH (N.D. Williams, pers. comm., 2017). Kakarla et al. (2002) found in groundwater applications that H_2O_2 concentrations between 5% and 20% were more effective than higher concentrations, but the increased reactivity of soil surfaces may require a higher concentration or repeated dosing. Villa et al. (2010) found that sequential additions of H_2O_2 improved TPH degradation up to 80% in a diesel-contaminated soil. The molar oxidant-to-hydrocarbon ratios used in our treatability study varied between 25 and 94 and should have delivered excess H_2O_2 for complete oxidation of the samples. Competitive reactivity with soil minerals may have occurred and warrants further investigation.

4 Conclusions

This treatability study found that Fenton's Reagent and Modified Fenton's Reagent with H₂O₂ concentrations of 3% and 10% applied to minimally processed McMurdo soils at 4°C had low to no effect on TPH concentrations over 3 weeks. This finding is in contrast to bench-scale studies that often use homogenized soil and stronger (30–50 wt%) H₂O₂ concentrations but is consistent with an in situ field study at Old Casey Station, Antarctica (Ferguson et al. 2004). Ex situ oxidative treatment of soil at McMurdo Station is likely feasible with the addition of mechanical homogenization, relatively high H₂O₂ concentrations, and repeated H₂O₂ treatments. For effective chemical oxidation of McMurdo Station soil, further study is needed, primarily of oxidant type and concentration, number of treatments, mineral catalyst (if any), soil processing, and reaction agitation. Given the high cost of operation in Antarctica, such optimization should be compared on a cost-per-ton basis to off-site disposal.

5 Recommendations

Based on the findings presented here and the results of prior studies in Antarctica, we recommend the following studies to assess the feasibility of remediating hydrocarbon-contaminated soils at McMurdo Station:

1. Optimization of peroxide chemical oxidation. There are a multitude of variable factors involved in peroxide-based treatment that may control remediation efficacy, including peroxide concentration, reagent-to-slurry ratio, catalyst type, catalyst-to-peroxide ratio, solution pH, treatment volume, and frequency of application. Further practical aspects of soil processing (e.g., sieving and mechanical homogenization) and reagent mixing should also be considered. For example, In-Situ Oxidative Technologies, Inc. offers a commercial modified Fenton's Reagent technology for petroleum compounds.
2. Alternative chemical oxidants. Other oxidative treatments may more effectively degrade hydrocarbons at McMurdo Station. Oxidants such as permanganate, persulfate, percarbonate, and ozone have been demonstrated for various organic contaminants (Siegrist 2010). For example, Regenesis, Inc., offers two oxidative products based on percarbonate and persulfate that it markets for treatment of petroleum hydrocarbons.
3. Biopiles. Excavation of contaminated soils, amendment with fertilizers, construction of piles, and periodic mechanical turning can accelerate the natural biodegradation of organic contaminants. McWatters et al. (2016) used biopiles to treat 590 m³ of diesel-contaminated soil at Casey Station, Antarctica, reducing TPH concentrations from 3500 mg/kg to 900 mg/kg over 5 years.

Prior to further studies, we recommend identifying fundamental constraints on any remediation technology:

1. Cleanup volumes and target levels. The volume of soil and concentration level to which contaminants must be reduced are major controls on the logistics and overall success of remediation efforts. If a technology cannot achieve target concentration levels, then it may be no more beneficial than off-site disposal. Further, the volume and cleanup level dictate the amount of reagents (oxidants and catalysts for chemical oxidation and fertilizers

for biopiles) needed for remediation and their overall external effects on environmental quality (e.g., nutrient runoff, soil pH, and soil structure).

2. Ex situ versus in situ treatments. In situ treatment of contaminated soil is often desirable but less effective than ex situ treatment. Ex situ treatment generally ensures that the treatment has complete and frequent interaction with the contaminants. The preremediation decision on ex situ versus in situ treatment will inform feasibility studies and expectations for treatable soil volumes and target contaminant levels.
3. Energy and materiel requirements for processing. Ex situ treatments require processing steps such as sieving, particle size reduction, and mechanical agitation that are both energy intensive and use specialized equipment. The availability of equipment and personnel to initiate and maintain treatments must be considered.
4. Treatment byproducts and effects. Most treatments involve relatively innocuous chemicals, such as peroxide, which degrades contaminants to water and carbon dioxide; but classical Fenton's Reagent requires soil acidification with strong acid. Highly fertilized biopiles may leach excess nutrients into waterbodies. Some of the oxidative treatments have strongly exothermic reactions that could heat surrounding soil during in situ treatments and affect soil structure, particularly permafrost. Removal of contaminated soil during ex situ treatments may affect soil structure, especially on permafrost where the active layer in adjacent soils may be affected.

Identifying an effective treatment, or suite of treatments, for hydrocarbons at McMurdo Station could significantly save costs compared with off-continent disposal. However, prior to large-scale implementation, further study is needed to identify such treatments to evaluate their potential overall impacts.

7. PERFORMING ORGANIZATION NAME(S) AND ADDRESS(ES) U.S. Army Engineer Research and Development Center Cold Regions Research and Engineering Laboratory 72 Lyme Road Hanover, NH 03755-1290					8. PERFORMING ORGANIZATION REPORT NUMBER ERDC/CRREL TR-20-5	
9. SPONSORING / MONITORING AGENCY NAME(S) AND ADDRESS(ES) National Science Foundation Office of Polar Programs Antarctic Infrastructure and Logistics 2415 Eisenhower Avenue Alexandria, VA 22314					10. SPONSOR/MONITOR'S ACRONYM(S)	
					11. SPONSOR/MONITOR'S REPORT NUMBER(S)	
12. DISTRIBUTION / AVAILABILITY STATEMENT Approved for public release; distribution is unlimited.						
13. SUPPLEMENTARY NOTES Engineering for Polar Operations, Logistics, and Research (EPOLAR) EP-ANT-18-80, "Hydrogen Peroxide / Fenton's Reagent Treatability Study of McMurdo Station Hydrocarbon-Contaminated Soil"						
14. ABSTRACT Hydrocarbon-contaminated soil is distributed heterogeneously at McMurdo Station, Antarctica, which has served for over 60 years as the logistics hub for the U.S. Antarctic Program. Here we investigated the treatability of McMurdo Station's contaminated soil with chemical oxidation. Our study collected five soil samples in 2018 and 2019, of which two contained high levels (>100 mg/kg) of total petroleum hydrocarbons (TPH) suitable for the treatability study. One soil (ITC) was characterized by 1250 mg/kg of predominantly midrange (n-C8 to n-C16) hydrocarbons, and the other (Soil Pile) was characterized by 3500 mg/kg of predominantly heavy molecular weight (>n-C21) hydrocarbons. We investigated the treatability of these soils with both Fenton's Reagent (pH < 3 with Fe2+) and modified Fenton's Reagent (chelated Fe2+), each with hydrogen peroxide concentrations of 3% and 10%. Soil slurries were placed on a shaker table at 100 rpm and 4°C for up to 21 days. TPH concentrations were reduced by approximately 50% for ITC; however, the oxidative treatments did not out-perform controls. All treatments and controls yielded no significant reduction in Soil Pile TPH. Poor performance by these chemical oxidation treatments indicates that remediation of hydrocarbons at these sites may require further soil processing in combination with chemical oxidation or alternative treatment technologies.						
15. SUBJECT TERMS Advanced oxidation processes, Chemical oxidation, EPOLAR, Fenton's reagent, Fuel spill cleanup, McMurdo Station (Antarctica), NSF, Soil pollution, Soil remediation, Total petroleum hydrocarbons, United States Antarctic Program
